Among various manufacturing processes, machining is the most common process used for the fabrication of parts and components from the aluminum alloys for aerospace, automotive, and structural applications. Aluminum alloys are known to have good machinability using most of the conventional machining processes due to providing high level of surface finish, longer tool life, and ease of machining into complex-shaped parts. However, with the increased focus on improving the strength, hardness, and wear resistance of aluminum alloys, the machinability of aluminum alloys has become more challenging. In recent years, the machining of aluminum-based MMCs and alumina-based ceramics has become one of the top priorities of research. There have been many investigations on the machinability of various aluminum alloys, aluminum MMCs, and alumina ceramics at macro and micro scale. The current trend of miniaturization of devices put micromachining at the forefront of the micro- and nanotechnologies. While many of the micro- and nanotechnologies are still in the laboratory development, micromachining has already been adopted by many industries for fabricating parts, components, and devices at micro scale. Some of the applications areas of micromachining include optics, electronics, medicine, biotechnology, communications, and avionics, to name a few.^[16] Some of the specific applications of micromachining include microscale fuel cells, fluidic microchemical reactors requiring microscale pumps, microscale valves, mixing devices, microfluidic systems, microholes for fiber optics, micronozzles for high-temperature jets, micromolds, and so on.^[16–17] The use of aluminum and its alloys in various types of micromachining processes is growing. There has been a significant amount of research on the machinability of aluminum alloys and MMCs, and alumina ceramics using various conventional and non-conventional micromachining processes. Some specific examples on the micromachining of aluminum include machining of microchannels for aluminum heat exchanger,

machining of micro fins for aluminum heat sink, fabrication of aluminum microscale pumps, aluminum micro molds for plastic industries, and so on.^[18–20]

This article aims to include the state-of-the-art research works on the machining of all types of aluminum-based alloys, composites, and ceramics at micro scale. The micromachining of aluminum has been discussed under two broad headings based on the major classification: conventional micromachining and nonconventional micromachining. Various types of conventional and non-conventional micromachining processes have been discussed in brief in addition to presenting the research works on micromachining of aluminum alloys using that specific type of micromachining process. Finally, the challenges and the future direction in the research of micromachining of aluminum has been discussed in the “Conclusion and Outlook” section.

CONVENTIONAL MICROMACHINING OF ALUMINUM ALLOYS

Micro Milling of Aluminum Alloys

Micro milling is one of the most widely used micromachining processes. It is the direct scale-down of the conventional macroscale milling process and is similarly capable of producing three-dimensional features in a wide variety of work materials including metals, ceramics, and polymers. Some of the applications of the micro milling process include precision biomedical components, micro propellers, micro-fluidic devices, micro-heat sinks, micro-heat exchangers, and X-ray lithography masks.^[21] Figure 1 shows the geometry of the micro milling setup (Fig. 1a) and the micro milling cutting tool (Fig. 1b).^[21] As shown in Fig. 1a, the computer numeric control (CNC) mill positions and translates the tool with respect to the workpiece to achieve the desired depth of cut and feed rate. The tool is connected to a high-speed spindle that rotates at typically 5,000–40,000 rpm and follows the geometry of the contour to be machined.

There have been a number of studies on the machinability of aluminum alloys using the micro milling process and investigating the effect of operating parameters on the micromachining performance of various aluminum alloys. Rao et al.^[22] investigated the machinability of 7075-T6 aluminum in high-speed face milling using carbide and diamond tools. It was found that high chip flow angles, high shear angles, low thrust forces, and thinner chips resulted from high cutting speeds. It was also found that higher feeds led to shear localization that created continuous chips. Higher residual stresses resulted from an increase in feed, whereas lowered the residual stresses resulted from an increase in cutting speed and depth of cut. It was also found that the surface roughness worsened when the depth of cut increased. Kiswanto et al.^[23] studied the effect of the spindle speed, feed rate, and depth of cut on machining time, surface roughness, and burr formation during micro milling of aluminum alloy AA 1100. Micro milling was completed on a miniaturized machine with two-flute flat end-mill tools. Statistical methods were used to predict the relationship among the variables. It was found that the surface roughness improved when lower feed rates were used. It was also found that the formation of burrs was heavily influenced by the condition of the cutting tool. Figure 2 shows the comparison of machined slots and tool wear after micromachining of AA 1100 for 15, 30, and 45 min. It was found that the formation of burrs as well as the tool wear increased with the duration of machining. As machining continued for a longer time duration, the tool wear increased making the tool blunt, which in

turn increased the burr formation and surface roughness of the micro slots. The average surface roughness (R_a) of the machined slot was found to significantly increase from 35 to 152 nm when machining duration was doubled, and to 275 nm when machining time was increased three times. It was also found that the tool wear became very significant and the tool became ineligible for further use after machining for 30 min.

Lee et al.^[24] studied the effect of chip load, cutting speed, and depth of cut on the surface roughness in the micro milling of Al 6061. It was found that one of the cutting edges created a deeper cut than the other edges because of run-out. It was also found that chip load had a large impact on surface roughness, especially when observed with cutting speed. An improved surface is attainable by improving run-out as well as implementing optimal machining parameters defined by the experimental data. It was reported that as chip load increased, the average surface roughness of the machined slots also increased. This study reported two important findings that are important to consider in micro milling: (1) the tool run-out should be minimized to zero to improve the machining accuracy, and (2) the chip load has a large effect on the machining surface roughness in micro milling. Kuram et al.^[25] analyzed the effect of the spindle speed, feed per tooth, and depth of cut on the tool wear, cutting forces, and surface roughness of the specimen during ball nose micro end milling of Al 7075. It was found that micro milling resulted in adhesion and abrasion tool wear mechanisms along with plastic deformation of cutting tools. As the spindle speed and

depth of cut increased, tool wear increased and the surface roughness decreased with higher spindle speeds, lower feeds per tooth, and lower depth of cuts. Kim et al.^[26] investigated the effectiveness of diamond end mill to achieve high-quality surface finish in micro milling of Al 2024. The diamond end mill was chosen because of its sharper edge, lower coefficient of friction, and higher thermal conductivity, resulting in a lower cutting temperature and higher speed for better surface accuracy and finish. The experimental tests revealed that it was possible to machine a mirrorlike surface on Al 2024 with the diamond end mill at high speed. Kim et al. also concluded that further finishing processes were not needed. It was also determined that the axial depth of cut had the biggest effect on the surface quality and that a low axial depth of cut, high cutting speed, and low feed per tooth should be used for optimal results. Vasquez et al.^[27] studied the effect of spindle speed, depth of cut per pass, feed per tooth, and coolant application for micro milling of aluminum and copper. It was concluded that the aluminum generated better micro-channels compared to the micro-channels in the copper specimen. It was also found that the width of the micro-channel can be better controlled when higher feed rates are used. Lastly, machining with a coolant aided in generating micro-channels with improved surface finish at the bottom of the channel. Vakondios et al.^[28] studied the effect of the axial depth of cut, radial depth of cut, feed rate, and inclination angle on the surface finish during ball end micro milling of Al 7075-T6. The milling strategies consisted of vertical, push, pull, oblique, oblique push, oblique pull, down, and up milling. It was concluded that the models accurately predicted the surface roughness for the ball end milling as obtained in the experimental data. The studies by Kuram et al.,^[26] Vasquez et al.,^[27] and Vakondios et al.^[28] mostly explain the effect of operating parameters on performance characteristics during micro milling of various aluminum alloys. These studies could be helpful to the industries to select the range of parameters and appropriate cutting tools for micro milling of aluminum alloys.

One of the major problems of the micro milling process is the unpredictable tool life and premature tool failure. Tansel et al.^[29] studied the tool life and tool failure from using micro end mills to machine aluminum, graphite, and

mild steel specimens. The cutting edges were observed and inspected to locate fatigue and extensive stress failure mechanisms, while the cutting force was tracked throughout the process. It was evident from the machining experiments that there existed a relationship between tool condition and feed direction of cutting force in the static part. Tool condition was indicated by wear, cutting edge damage, and small particles stuck on the surface of the tool. Segmental averages and wavelet transformations were both used to predict the tool breakage. The static part of the feed direction force indicated a worsening tool condition. It was concluded that the static part of the feed direction and feed rate adjustments lead to an increased tool life from use of high feed rates and minimal breakage. Figure 3 shows the comparison of the tool wear after machining various lengths in aluminum.^[29] It can be seen that the adhesion of chips increases significantly with the increase of the cutting length and duration during machining of aluminum. There is also tool wear from the cutting edges reducing the diameter of the cutting flute after prolonged machining. In addition to chips, there could be some adhesion from the cutting fluid or coolant to the tool surface. Ultrasonic cleaning of tools in the acetone or alcohol would be able to clean those adhered substances from the tool. After cleaning, the cutting tool could be reused if the cutting edges remain unaffected.

There have been many different approaches taken by the researchers for monitoring tool wear condition during the micro milling of aluminum alloys. A smart workpiece holder was proposed by Tansel et al.,^[30] which enabled proper monitoring of cutting force and predicted the potential for tool breakage. The tool consisted of an actuator that generated a move opposite of the feed direction, while the overall feed rate was reduced. When the tool was used, the feed direction cutting force increased and fluctuated more than without using the tool. It was also possible to predict tool breakage sooner so that chip removal rate could be decreased to increase the tool life. Tansel et al.^[31] also proposed acoustic emission (AE) signals for detecting tool breakage and predicting tool condition. In order to detect tool breakage, the AE signals were separated with a narrow bandwidth, a bandpass filter, and an analog hardware to recognize the upper values of the harmonic signal. The

signal values were transformed into digital data and sorted from the machining process using the Adaptive Resonance Theory and Abductory Induction Mechanism. The tool wear was then estimated using the data and then tested for confirmation. Micro end mills were used with two-fluted tools on mild steel and aluminum. It was concluded that the machining process had very low noise and the predictions for tool breakage was accurate. It was found that AE was advantageous because it was independent from the cutting direction, but certain conditions led to high noise levels, especially with thin specimens. The studies by Tansel et al.^[29–31] provide an in-depth understanding of the tool wear mechanism and propose successful strategies of reducing the tool wear during micro milling of aluminum alloys. The proposed on-machine tool wear monitoring systems could be applied to micro milling of other difficult-to-cut materials to reduce the chance of sudden tool failure and to improve the product quality.

Tool life and cutting performance are vital to the overall machining success and can be enhanced by protective tool coatings. In order to accomplish longer tool life, a hot-filament chemical vapor deposition process was used on tungsten carbide micro end mills to produce a thin coating on the tool.^[21,32] Figure 4 shows the scanning electron microscopic (SEM) images of the uncoated carbide tools and fine grain diamond (FGD)-coated carbide tools that were used for micro milling of 6061-T6 aluminum.^[32] The tests allowed for analysis of tool wear, coating integrity, and chip morphology. It was reported that tool integrity improved with the coated end mill along with a resulting

lower wear rate, reduced cutting forces, and no signs of aluminum adhesion. It was found that diamond films can be successfully used in micro end milling to improve surface roughness. It was also reported that the chip morphology improved when diamond-coated carbide tools were used.

The cutting forces generated during micromachining is another important factor to consider. There is a direct relationship between the cutting forces and the tool tip temperature. Yang et al.^[33] studied the effect of the tool edge radius on the cutting forces and the tool tip temperature on a micro-cutter during micro end milling of Al 2024-T6. A mathematical simulation was developed along with an experimental process. It was found that cutting forces increased when tool edge radius increased. As shown in Fig. 5, both normal and axis forces increased gradually with time, whereas the feed force increased first and then decreased over the machining time.^[33] For all three forces, the higher the tool edge radius, the higher the cutting forces. This effect led to the maximum effective stress and cutting temperature of the tool in the area from the rake face to the tool edge corner and flank face. It was also found that an increase in tool edge radius led to a decrease in effective stress and mean cutting temperature. Overall, the tool edge radius had the largest effect on the distribution of temperature on the microscale cutting tool.

Tansel et al.^[34] studied the effect of cutting forces on the tool wear during micro end milling of aluminum alloy and steel. The goal was to determine the precise usage for a

tool used in micro end milling operations as tool wear and cutting forces both change depending on other machining conditions. Neural networks were used to predict the tool usage, and a method for calculating the wear was developed. These tests concluded that the effectiveness of the cutting edge decreased as machining continued, though cutting forces allowed for easy predictions of tool condition. It is necessary that the feed and thrust cutting forces be measured from the same machining parameters for this to be possible. The model proposed in the study successfully predicted the tool wear and condition during micro end milling, allowing for tool life estimations before experiments were conducted. Bissacco et al.^[35] studied the cutting forces associated with micro milling of aluminum alloy and steel in order to develop a model for prediction. A theoretical model was developed based on the cutting edge radius size effect, tool run-out, and chip flow angle deviation in relation to inclination angle. Cutting tests were completed, and the cutting forces and chip thickness were monitored at varying machining parameters. It was found that the predicted and experimental forces were in agreement and the model developed was validated. It was also found that the unbalanced force from tool run-out increased the tool deflections. The cutting forces, tool tip temperature, and tool wear are interrelated, as established by Yang et al.^[33] and Tansel et al.^[34] With the help of the theoretical model developed by Bissacco et al.,^[35] the cutting forces can be estimated based on the machining conditions. However, the authors could further focus on enhancing the capacity of the model by establishing the correlation between cutting forces and the tool tip temperature.

Nevala et al.^[36] developed an atomization-based cooling and lubrication system in order to eliminate the collision force that traditional jet coolant could impose on the micro milling tool and could hinder the cutting accuracy during micro milling of Al 6061-T6. The authors claimed that traditional flood cooling processes were unsuitable for micro milling due to the collision force between the fluid stream and the tool being large enough to affect the accuracy of the cutting process. However, the atomization-based cutting fluid induced very minimal to no collision force on the cutting tool in micro milling. The system consisted of two nozzle streams that direct cutting fluids toward the micro milling tool. The necessity of cooling and lubrication was evaluated using this system through micro milling experiments. Two different cutting fluid concentrations were used in the process by using deionized water, and dry cutting was completed for comparison. It was concluded that when using deionized water, the relationship between cooling and lubrication was significant in micromachining.

Often, tools needed for micro milling are smaller versions of macro milling tools having the same tool geometry and, hence, breaks more frequently during micromachining. Therefore, several researchers have investigated the feasibility of modifying the cutting tool geometry and

applying modified cutting tools for improved micromachining performance of aluminum alloys. Cheng et al.^[37] introduce a new model for micro tool fabrication based on machining conditions and restraints. First, the general guidelines of micro milling tools were evaluated, and single-slot milling tests were conducted with the polycrystalline diamond (PCD) end mills made from tungsten carbide. Guidelines for the custom micro milling tool were then created based on various conditions observed from the experiments. The optimal design involved a modified hexagonal end mill, and the tool was made by wire electrical discharge machining (WEDM). The tool was used in milling tests resulting in an improved surface finish with high accuracy on both the side and the bottom. Figure 6 shows the comparison of the tool geometry and the machined surface finish between the commercially available two-flute end mill and the in-house fabricated PCD hexagonal end mill.^[37] It was reported that the surface roughness of the micro slots machined by fabricated PCD hexagonal end mill were comparable to those machined by commercial two-flute end mill.

Adams et al.^[38] conducted micro milling experiments on 6061-T4 aluminum by creating tools from high-speed steel and micro-grain tungsten carbide. These micro end mills were made using focused ion beam sputtering, a process that provides feature size control and allows for a variety of tool geometries. It was found that the focused ion beam sputtering technique could be applied to the fabrication of smaller tools so long as the microstructures are suitable and satisfy the strength and toughness needed for machining. It was evident that the use of this new technique for micro tool fabrication was successful and led to further development in the micromachining industry. Figure 7a–c shows the micro milling tools with two, four, and five cutting edges fabricated by focused ion beam sputtering.^[38] The machined slots are shown in Fig. 7d,e. Figure 7d shows the micro slots in brass machined by the micro end mill tool having five cutting edges. Figure 7e shows the scanning electron micrograph of micro slot in Al 6061 machined using the single two-facet micro end tool.

Micro-WEDM is another process that could be used to fabricate micro milling tools. Chern et al.^[39] fabricated tungsten carbide micro end mills using micro-WEDM and used the fabricated tools to machine Al 6061-T6 alloy. The fabricated tools were found to successfully machine Al 6061-T6, and four different types of burrs were generated: primary, feathery, needlelike, and minor burrs. Figure 8 shows the machined micro slots as well as primary, feathery, needlelike, and minor burrs.^[39] It was found that minimizing the axial engagement and feed will help in avoiding severe burr formation in micro milling.

Although several novel processes of fabrication of cutting tools for micro milling have been demonstrated,^[37–39] the applicability of those fabricated tools may be limited. One of the major reasons for limited capability of the fabricated tools is the limitation in shape and geometry

of the cutting tools. In addition, WEDM and electron beam process would create recast layers on the machined surface, which may further promote the tool wear in the form of chipping and reduce the strength of the cutting tools. Moreover, the chip formation process using the fabricated tools may not follow the conventional method of chip formation, and hence, ploughing process may dominate in some cases instead of shearing process.

Micro-Turning of Aluminum Alloys

Micro-turning is one of the most important mechanical micromachining processes. It is capable of fabricating miniaturized part from a wide range of engineering materials including aluminum alloys. Most of the aluminum alloys, except aluminum-based MMCs and alumina ceramics, have good machinability using the mechanical micromachining processes. Although the basic principle and setup for the micro-turning process is almost similar to the macroscale turning process, there are several differences in the microscale cutting operations, mainly due to the fact that chip thickness in micromachining applications is comparable in size to the edge radius of the tool, resulting in large negative rake angles and elastic-plastic deformations of workpiece materials. Figure 9 shows the basic geometry and definition of cutting parameters and deformation zones in turning operation.^[40]

Micromachining relies on the optimization of process parameters to improve productivity and quality of the finished surface. Tool edge radius and minimum chip thickness are the two important parameters influencing the micro-turning performance. The minimum uncut chip thickness indicates the depth at which material is ploughed, and tool edge radius is the radius of the roundness at the tool tip. Malekian et al.^[41] developed analytical models to determine the minimum uncut chip thickness as a function of tool edge radius and the friction coefficient. To validate the models, experiments were conducted using micro-turning of aluminum 6061 with a rounded-edge tungsten carbide tool at various depths of cut. It was found that the minimum uncut chip thickness increased as the friction angle increased which led to ploughing. It was also found that the use of lubricants, higher thrust forces, or smaller edge radii could decrease the minimum uncut chip thickness, which in turn could improve productivity.

Ng et al.^[42] explored the effect of undeformed/uncut chip thickness and cutting speed on chip geometry, cutting forces, and surface roughness during micro-turning of Al 7075-T6. A single crystal diamond tool was used due to its sharp cutting edge. The tests revealed that when the minimum undeformed chip thickness was reached, continuous chips were generated. It was also found that when the undeformed chip thickness was larger than the tool edge radius, it had a linear relationship with the cutting force and a size effect was observed. Ng et al. determined that when tool-chip contact temperature decreased with decreased undeformed chip thickness, the mean friction coefficient had a size effect. It was also found that when the undeformed chip thickness was smaller than the edge radius of the tool, the surface was rougher irrespective of the cutting speeds. Figure 10 shows the effect of the undeformed chip thickness on the cutting force and specific cutting energy for the micro-turning of Al 7075-T6.^[42]

Fang et al.^[43] examined the effect of tool edge geometry in machining three different aluminum alloys due to the high demand of finish hard turning and micromachining. During the experiments with alloys 7075-T6, 6061-T6, and 2024-T351, chamfered and honed tools made of cemented

carbide were used at various cutting speeds and feed rates. Process parameters, including cutting force, thrust force, cutting-to-thrust force ratio, and chip thickness, were measured during the turning operations. A model

was developed for the slip line of chip formation indicating the special area of plastic deformation with negative rake angles. The model suggested that there existed a cutting force between the flank sides and the tool rake when a dull tool edge was used. Fang et al. concluded that if the uncut chip thickness was smaller than a specific value, the thrust force was larger than the cutting force. Comparatively larger cutting forces were found with the chamfered tool. The machinability of three aluminum alloys was compared in terms of cutting forces, as can be seen in Fig. 11.^[43] The aluminum alloys were machined into a tubular form with the outer diameter of 50 mm and the tube thickness of 3 mm for use in subsequent orthogonal cutting tests. It was found that Al 7075-T6 and Al 2024-T351 generated very close cutting force F_c in most cutting tests. Al 6061-T6 produced the smallest cutting force among the three aluminum alloys, indicating better machinability in the micro-turning process.

Liu et al.^[44] explored the reasoning behind the size effect in micro-turning of Al 5083-H116 with respect to tool edge radius and characteristic length scale. It was found that the specific cutting energy along with decreased uncut chip thickness resulted in the size effect in micro-turning. A finite-element model for orthogonal cutting was developed based on strain gradient plasticity and then used to analyze the size effect based on the tool edge radius. Figure 12 shows the finite-element model of the chip formation process for different values of “ t/r ” ratio (ratio of the uncut chip thickness t to the tool edge radius r). Liu et al. determined that the tool edge radius partly justified the size effect during micro-turning in terms of the material deformation process. The tool edge radius changed the material flow pattern through the plastic shear zone and caused high-energy dissipation. There was an increase in specific cutting energy under low cutting speeds with small uncut chip thickness and insignificant tool edge radius. The tests also revealed that there was no increase in specific cutting energy when the uncut chip thickness was the same as the tool edge radius. Figure 12 shows the variation of the specific cutting energy with uncut chip

Fig. 11 Comparison of cutting force, F_c , and thrust force, F_r , against the uncut chip thickness for micro-turning of three different aluminum alloys. Workpiece: outer diameter = 50 mm; tube thickness = 3 mm; cutting speed = 500 m/min

thickness and the ratio of the uncut chip thickness t to the edge radius r for two edge radii.^[44] The studies presented in references^[41–44] demonstrate the significance of an important parameter in turning: the uncut or un-deformed chip thickness. For every single material, there is a critical un-deformed chip thickness, below which the cutting process is dominated mostly by the ploughing actions. Besides the cutting mechanism, the uncut chip thickness influences the overall micro milling performance.

Tool wear is an important issue in the micromachining of aluminum alloys. There have been several studies on investigating the tool wear mechanism in micro-turning of aluminum alloys. List et al.^[40] discussed the derivation of tool wear in dry machining of aluminum alloys in effort to minimize tool wear and improve the machining process. Adhesion and diffusion are two of the most important causes of tool wear due to the presence of edge buildup and an adhesive layer on the tool rake face, as shown in Fig. 13.^[40] These effects lead to a decrease in shape and dimensional accuracy and tool cutting efficiency, while the surface quality is lowered. List et al. conducted cutting tests on an aluminum–copper alloy with an uncoated cemented carbide tool and the machining results were observed. It was found that the built-up edges were formed at low cutting conditions on the rake face of the tool and impede on the cutting edge. Tool wear increased due to continuous sliding of material fragments which caused abrasion on the tool rake face. It is suggested that a larger rake angle and a polished tool surface be used at low cutting speeds to reduce adhesion. On the other hand, severe

Fig. 13 SEM images of a polished tool section after used for machining for 7 min showing (a) the built-up edge and (b) the detail of the asperities. Cutting conditions: $V_c = 60$ m/min; $\alpha = 15^\circ$; $f = 0.1$ mm/rev; $w = 4$ mm. The tool was cut into two pieces by wire electro erosion (perpendicularly to the rake face) and polished

Source: From List, Nouari, Gehin, Gomez, Manaud, Le Petitcrops, and Girot.^[40] ©2005 Elsevier, All rights reserved.

cutting conditions led to a thin built-up layer on the tool surface. Otieno et al.^[45] developed a method to predict the cutting forces and temperatures using finite-element analysis with the addition of a software program. Machining with aluminum T6061 was simulated on the software with downmilling using a K10 carbide two-fluted end mill with specific conditions. Otieno et al. concluded that cutting forces decreased with an increased cutting speed. It was also found that the machinability of a material was heavily dependent on the depth of cut, while the feed rate had a lower influence on the cutting force. Overall, the conditions for machining, including the feed and depth of cut, can be predicted for a given cutting speed to reduce the effect of tool wear. The relation of cutting forces with the

cutting speed reported by Otieno et al.^[45] may be limited to a range of cutting speeds. During turning, the cutting forces usually decrease first with an increase in the cutting speed up to a certain range, then again start to increase with an increase in the cutting speed. Therefore, future study should focus on investigating the effect of a higher range of cutting speeds on the cutting forces to obtain more accurate information.

The aspects of micro- and nano-cutting were analyzed in effort to examine their effects on the machined surface finish. The final machined surface depends on various dynamic factors including material properties, tooling, process parameters, servo accuracy, mechanical structural stiffness, and nonlinear factors. Zhou et al.^[46] developed an approach to relate the machined surface with the operation conditions using an integrated simulation. Emphasis was placed on cutting process variations and their impact on both texture formation and surface topography. Experiments were conducted to verify the developed models using Al 6061 specimens. Zhou et al. concluded that the machining performance can be optimized through parameter control to enhance the surface quality of the specimen. The models were able to accurately interpret the surface topography and indicate the process settings for accurate machining. It was also found that surface roughness was influenced by the material heterogeneity of the workpiece. Ding et al.^[47] examined the effect of hard particles when micro-cutting an aluminum alloy based on the assumption that they had a large role in the formation of defects and cracks. In order to examine this assumption, micro-cutting experiments were completed using a micro-tool made from the focused ion beam. Process conditions were specified and cutting was completed without a coolant on Al 6061. Ding et al. observed that micro-cutting of Al 6061 with hard particles resulted in voids on the machined surface and subsurface. It was determined that these hard particles were brittle and might led to cracks on the machined surface. Voids would then form as the cracks spread due to the hard particle initial fragmentation. The SEM observations also revealed dislodged hard particles on the machined surface. In terms of machining conditions, a reduced feed rate resulted in ductile mode machining in which hard particle cracks were avoided. It was found that there were more cracks around the hard particles when a feed rate of 5 $\mu\text{m}/\text{rev}$ was used. On the other hand, there were very few cracks on or adjacent to the hard particles when a lower feed rate (0.25 $\mu\text{m}/\text{rev}$) was used.

Liu et al.^[48] performed turning, grooving, and milling on aluminum alloys using a single-crystal diamond tool to generate a mirror surface and lenticular lens array. The experiments concluded that there existed striations on the machined surface, and they were eliminated by further optimization based on the angular increment and arc length increment during machining. It was found that the machined lenticular lens surface quality was dependent on

the microstructure of the material as well as the thermal stability of the cutting tool. Overall, Liu et al. concluded that milling was able to generate the best surface integrity and accuracy on the aluminum lenticular lens array. Although the authors claimed that milling process could generate better surface integrity and accuracy compared to turning process, the claim could be application dependent. Turning and milling are two separate processes with a focus on different applications. Therefore, comparing two processes for a single application may not reflect accurate capability of the processes.

Besides micro-turning of aluminum alloys, there have been several studies on the micro-turning of single-crystal aluminum. Sato et al.^[49] conducted micro-cutting tests on aluminum single crystals in effort to determine the accuracy of high-precision machining. Several process parameters directly impacted the success of the machining process, including specifications in the cutting machine, cutting tool, material machinability, cutting mechanism, and cutting condition. Cutting conditions include the cutting speed, depth of cut, tool shape, and cutting oils. Cutting was completed with single-crystal aluminum in dry conditions, and the results were analyzed at various orientations. Sato et al. concluded that at a specific depth of cut, the size effect existed along with the alternation phenomenon. It was also found that the cutting direction determined the roughness and flatness of the surface of the finished product, supporting the conclusion that specimen orientation can be used to improve machining accuracy. Lee et al.^[50] developed a micro-plasticity model for predicting the shear angle along with a model to determine the cutting force based on a friction variable for diamond-turned crystalline materials. It was found that crystallographic orientation of the material along with the chip and tool face friction determine the fluctuation pattern of the micro-cutting forces. Lee et al. also concluded that the pattern and period of the cutting force fluctuations was also dependent on the frictional effect. Lastly, this study revealed that using the cutting force model to predict the power spectrum based on the friction variable is a viable option for diamond turning operations. Kota et al.^[51] reviewed the machining of single-crystal aluminum based on modeling and experimentation to explore further testing. It was evident that crystallographic anisotropy had a large impact on machining forces in addition to rake angle, cutting velocity, and uncut chip thickness. Plunge turning and planing tests were done on single-crystal and coarse-grained aluminum using a single-crystal diamond tool. Kota et al. found that coarse-grained aluminum planing resulted in variation in the specific energy and surface roughness depending on the crystallographic anisotropy. It was also seen that machining forces from planing and plunge turning were comparable. Lastly, the experiments determined that deformations led to lattice rotation at a depth equal to that of the cutting depth.

Micro-Grinding of Aluminum Alloys

In the micro-grinding process, a microscale grinding wheel (1–999 μm), is used to conduct finish machining on a work material. The grinding wheels are made of diamond or alumina abrasive particles embedded in a solid matrix. The finer the abrasive particles, the smoother the machined surface finish. There have been a few studies on the micro-grinding of aluminum and its alloys. The main reason is the ductility of aluminum alloy at high temperature generated during grinding. There is adhesion of aluminum on the grinding wheel making the grinding process instable. Besides, aluminum alloys already have excellent machinability in conventional milling and turning operations, and the surface finishes produced by milling and turning processes do not require any further finishing operation. However, the grinding operation was found to be more effective for machining aluminum-based MMCs and alumina ceramics. This is due to the fact that both aluminum-based MMCs and aluminum-based ceramics are hard to machine using conventional milling and turning operations, and hence are suitable candidates for grinding operations.

Kwak et al.^[52] performed grinding operations on aluminum enforced with SiC particles and Mg powder. The goal was to observe the factors that influenced the grinding process and to optimize the grinding conditions. An MMC was fabricated under a nitrogen gas atmosphere from an AC8A aluminum alloy with SiC and Mg reinforcement. The amount of SiC and Mg for optimum results was determined from the fabrication experiments. Kwak et al. utilized the Taguchi design of experiment to evaluate the grinding parameters and indicate the optimum settings. Lastly, the model's effectiveness was verified based on the surface models developed. Zhong et al.^[53] performed

grinding on aluminum-based MMCs in an effort to understand the machinability of MMC in grinding. The process parameters that were observed include surface roughness, grinding force, abrasive type and size, conditions for grinding, and subsurface integrity. Two different aluminum composites enforced with Al_2O_3 particles were used for the experiments with a SiC wheel. The surface roughness was observed after machining, and it was reported that the surface roughness decreased significantly after fine grinding. Zhong et al. also found that during rough grinding, aluminum was smeared on the surfaces, whereas during fine grinding only, the Al_2O_3 particles were seen. Ductile streaks were visible at a specific depth of cut, and the Al_2O_3 particles and aluminum matrix were eliminated during the machining. No subsurface damage was identified, and it was evident that SiC wheels for rough aluminum grinding were very applicable and could be followed by fine grinding. Figure 14 shows the comparison of the subsurface of MMC after rough grinding and fine grinding.^[53] It can be seen that the subsurface generated on the aluminum MMC during fine grinding is comparatively smoother and has lesser micro-cracks than that during rough grinding.

Ilio et al.^[54] developed the models for predicting various process parameters for grinding of aluminum MMC and verified them through experimentation. Force components, cutting energy, and surface roughness of the workpiece were all examined in relation to their effect on the grinding process. Aluminum alloys 2009 and 6061 reinforced with silicon carbide powder and whiskers were used as the workpiece materials. Dry conditions were used, and the data were collected for model development. It was concluded that there was a linear relationship between the normal and tangential components of the grinding force. It was also found that the cutting component showed no

Fig. 14 Subsurface of ground alumina-based MMC (2618/ Al_2O_3 /20p): (a) rough grinding; (b) fine grinding

Source: From Zhong and Hung.^[53] ©2002 Elsevier, All rights reserved.

effects on the changes in sliding component of the specific grinding energy, supporting the exponential decrease as the removal rate increases throughout the process. A power relationship was identified for the workpiece roughness and equivalent chip thickness as it decreased linearly when hardness increased in the workpiece material.

Although there have been a few studies on the micro-grinding of aluminum MMCs, the results are promising. As conventional micro-turning and micro-milling processes are difficult to apply for the machining of MMCs due to reinforced hard particles, micro-grinding can be a suitable option to obtain comparatively smoother surface finish in aluminum MMCs. The nonconventional micro-machining processes such as micro-EDM, and laser micromachining could be an option for machining aluminum MMCs, but the surfaces generated in micro-EDM and laser micromachining are relatively inferior to those of grinding.

Micro-Drilling of Aluminum Alloys

The micro-drilling process is a mechanical micromachining process where a microscale (1–999 μm) drilling tool is used to machine micro-holes in the workpiece material. The drilling operation is carried out either vertically or horizontally in a CNC machine. Usually, solid carbide tools are used for the micro-drilling process; however, high-speed steel and other coated tools are also used based on the work materials and applications. Although there have been only few studies on the microscale drilling of aluminum alloys, micro-drilling can be used for many important applications of aluminum in automotive and aerospace industries.

Rajmohan et al.^[55] studied the effect of machining parameters on the thrust force, surface roughness, and

burr height in micro-drilling of aluminum-based MMC. Response surface methodology (RSM) and central composite design were used for evaluation and modeling. An Al 356 alloy was used for drilling, and the mathematical models were used to determine the relationships between inputs and outputs. The parameters considered included spindle speed, feed rate, and weight percentage of SiC. The predicted and actual values for the machining conditions were compared, and the machining performance was analyzed. Rajmohan et al. concluded that the central composite design was able to generate predictions for thrust force, surface roughness, and burr height. It was also found that feed rate and speed impacted the surface quality and decreased the thrust force and burr height.

Cho et al.^[56] fabricated a deburring tool intended for micro-holes in aluminum alloys. The deburring tool was rotated into the intersecting hole in Al 6061-T6, and the results were observed. Cho et al. found that the deburring tool was able to remove all the burrs successfully without too much cutting, though it was also revealed that higher speeds of revolution resulted in irregular cutting because of tool vibration. The curvature of the burr edge with similar primary and secondary hole diameters also resulted in the same outcome. It was also found that lower speeds of revolution and feed rate led to the depth of cut irregularities. Figure 15 shows the design and assembly of the fabricated deburring tool and the micro-holes before and after the deburring process.^[56] It can be seen from Fig. 15 that the fabricated deburring tool was able to successfully remove burrs from the edges of the micro-holes in Al 6061-T6 alloy. However, the micro-holes were enlarged from the original diameter after the deburring process. As shown in Fig. 15a, the cutter head of the deburring tool was hemispherical with a slot aligned at an angle ($\beta = 10^\circ$) to the shaft. With the slot angle, one of the two slot edges

Fig. 15 (a) Assembly and individual parts of the deburring tool and (b) micro-holes before and after deburring using the fabricated deburring tool. The points A, B, and C are the same marked positions in the images for before and after deburring in (b)

Source: From Cho and Kim.^[56] ©2012 Elsevier, All rights reserved.

functioned as a cutting edge, and the other edge functioned as a limiter to preclude excessive cutting of the burr edge. A portion of the cutter head was ground flat so that the head could easily enter the hole. The cutter head was mounted on a shaft pivoted at the grip and was forced in the radial direction by leaf springs. During the deburring process, the tool was inserted into the hole and was rotated counterclockwise with the retreat stroke until the cutter head passed through the burr zone. The disengaged radial position of the cutter head could be controlled by a stopper, as shown in Fig. 15a.

Due to the fact that lubricants can be harmful to the environment, methods are being developed to determine the optimal cutting conditions for machining. Kelly et al.^[57] determined the process parameters that most affect the drilling process and determine what cutting fluid should be used in micro-drilling. The experiments were completed on aluminum using steel twist drills and the results were evaluated. It was found that minimum quantity lubrication could enhance the machining performance for micro-drilling of aluminum alloy. The feed nozzle alignment with the tool, the cutting fluid volume flow, and the cutting fluid pressure could all be controlled to increase the tool life. Kelly et al. recommended further exploration of the particle size distribution by the lubrication system in order to determine other conditions in the machining. Micro-drilling and micro-milling experiments were conducted on Al 6061-T6 in order to determine the influence of cutting parameters on the final machined specimen.^[58] Burr shape and burr type were observed, and the most influential factors were indicated from the experimental results. Various cutting speeds, chip loads, and depths of cut were used in the milling process, and the feed-to-diameter ratios and cutting speeds were observed for drilling tests. Lee et al. concluded that burrs on the exit side existed irrespective of the cutting speed and feed in milling and increased in size when the feed rate increased. As higher cutting speeds were used, there was a decrease in the burr size and the type of burr depending on the tool behavior. Lastly, the drilling experiments concluded that

as the feed rate increased, the height and thickness of the burr increased.

NONCONVENTIONAL MICROMACHINING OF ALUMINUM ALLOYS

Micro-EDM of Aluminum Alloys

Micro-EDM is the process of machining electrically conductive materials in the form of microscale craters by means of precisely controlled electric sparks that occur between an electrode and a workpiece in the presence of a dielectric fluid.^[59] The basic mechanism of the micro-EDM process is essentially similar to that of the EDM process with the main difference being in the size of the tool used, the power supply of discharge energy, and the resolution of the X-, Y-, and Z-axis movement. The three main varieties of the micro-EDM process are die-sinking micro-EDM, milling micro-EDM, and WEDM, as shown in Fig. 16.^[60]

As shown in Fig. 16a, an electrode with desired micro-features is used on the workpiece in die-sinking micro-EDM to produce corresponding mirror images. In die-sinking micro-EDM, the tool electrode has the complementary form of the finished workpiece and literally sinks into the workpiece. In milling micro-EDM, usually tubular or cylindrical micro-electrodes are used to produce the desired complex shape by scanning, as shown in Fig. 16b. A cylindrical electrode rotates around its axis (Z-axis) with the scanning movements in X and Y directions. The contour of a particular layer is specified in the part program, and the final complex cavity is machined by 3D milling process with the help of electrical discharges. In micro-WEDM, a continuously traveling micro-wire is used to cut through a conductive workpiece according to the programmed path, as shown in Fig. 16c. The basic mechanism of micro-WEDM is the same as that of micro-EDM, and the material is removed as a result of series of electric sparks between the workpiece and the wire

Fig. 16 Schematic representation of (a) die-sinking micro-EDM, (b) milling micro-EDM, and (c) micro-WEDM

electrode. Since wire orientation can be changed by controlling the horizontal position of the upper wire guide relative to the lower guide, all types of ruled surfaces can be cut by micro-WEDM process.

Micro-EDM process is one of the most widely used micro-manufacturing processes used in industries. Although Al alloys have excellent machinability with conventional machining processes, EDM and micro-EDM are often used to machine intricate features in Al alloys for plastic injection molds and electronic applications^[59–60]. The major applications of micro-EDM are found to be in the machining of various aluminum alloys and MMCs and alumina ceramics, which are difficult to machine using conventional micromachining processes.

Aluminum Alloys

There have been several studies on investigating the machinability of aluminum alloys and studying the effect of operating parameters on the micro-EDM performance of various aluminum alloys. Jahan et al.^[61] experimented with micro-EDM drilling and milling processes to investigate the effect of various parameters on the machining behavior of AA 2024 alloy. Parameters included capacitance, resistance, supply voltage, electrode speed, and gap control, and the material removal rate, tool wear ratio, surface roughness, and machining depth all served as indicators of performance. A tungsten tool electrode was used in the tests and deionized water served as the dielectric material. Jahan et al. concluded that as capacitance increased and resistance decreased, the material removal rate, machining depth, and surface roughness all increased. It was also determined that higher supply voltages led to higher spark energy per pulse, resulting in an increase in material removal rate, machining depth, and surface roughness. Lastly, it was found that machining was faster when higher settings of voltage, feed rate, and gap control were used. Figure 17 shows a micro-slot machined

in AA 2024 aluminum alloy by the milling micro-EDM process.^[61]

Dave et al.^[62] studied the effects of machining parameters on the overall performance from machining micro-holes in aluminum using micro-EDM drilling. The Taguchi method was used for the experimental design, based on gap voltage, capacitance, pulse-on time as electrical parameters, and thickness and electrode rotation as non-electrical parameters. Tungsten was used as the tool electrode and Al 1100 was used as the workpiece. Dave et al. concluded that high electrode rotational speeds led to top and bottom radial overcuts and taper effects. It was also found that rotational motion reduced electrode depletion. The best conditions for reduced overcuts and taper angles were found using stationary electrode conditions, whereas low rotational speeds were found to be the best for electrode depletion. Electrode rotation was found to have a large impact on the other parameters, excluding electrode depletion. Lastly, the pulse-on time affected the bottom radial overcut, and the capacitance impacted the taper angle. Somashekhar et al.^[63] utilized an artificial neural network to create a model to optimize the machining parameters and to predict the material removal rate at optimum parameter setting. The micro-EDM experiments were conducted using a tungsten carbide tool and EDM synthetic oil to observe the effects of voltage, capacitance, feed rate, and speed. Comparison of the data from the model and from the experiments showed accurate predictions for material removal rate.

Tool electrode wear is a major concern in micro-EDM due to its effect on accuracy of micro-features and productivity. Pham et al.^[64] studied the influence of various parameters on the electrode shape deformation and variations in volumetric tool wear in micro-EDM. Three materials, namely, aluminum, steel, and brass, were machined with a tungsten carbide tool electrode in the form of rods and tubes. It was found that side sparking could be avoided when machining soft materials with certain machining strategies to provide effective flushing. It was also determined that there existed several uncontrollable factors that resulted in variation of the electrode wear ratio. In another similar study, Pham et al.^[65] conducted micro-EDM drilling experiments with micro rod and tube electrodes to determine the impact that different machining conditions have on the overall performance. Preceding the tests, a model to calculate the volumetric wear ratios was shown, and electrode shape deformation and random variation of volumetric wear were defined as the most influential parameters. Steel, brass, and aluminum were used as the materials, and tungsten carbide was used as the tool electrode material, whereas oil was chosen as the dielectric material. Pham et al. concluded that machining soft materials, such as aluminum, require good flushing, a result of avoiding side sparking. It was necessary to understand the influence of machining parameters in order to perform micro-EDM successfully. Figure 18 shows the comparison

of the effectiveness of tube and rod electrodes in terms of the depth of multiple micro-holes and tool wear for micro-EDM of aluminum alloy.^[65] It was found that for micro-EDM of aluminum, tube electrodes were more effective compared to rod electrodes. It can be seen from Fig. 18 that when tube electrodes are used, all the micro-holes machined in aluminum alloy have the same depth, and also the wear in the tube electrode is uniform for making the consecutive holes. On the other hand, both the machined depth and tool wear are nonuniform for micro-EDM of aluminum using rod electrodes.

Tsai et al.^[66] conducted micro-EDM experiments in an effort to study the thermal properties of electrode materials and their effect on electrode wear and machinability. Electrode wear ratio can be determined by the amount of electrode removal compared to the amount of material removed from the workpiece. Micro-EDM was used on several materials, including aluminum, to create through-holes using EDM oil and a rotating tool electrode. Tsai et al. concluded that high boiling point, melting point, and thermal conductivity resulted in a smaller volumetric wear ratio of the electrode irrespective of the material being tested. It was also determined that corner wear occurred for low thermal conductivity of the electrode. Tsai et al. determined an index for calculating the performance of the electrodes in micro-EDM based on the boiling point and its erosion property.

The advantages of micro-EDM, including its low cost and high precision, have led to the fabrication of *in situ* micro-electrodes. Lim et al.^[67] completed fabrication of micro-electrodes followed by micro-EDM using the fabricated electrodes to assess the performance of the electrodes based on the material removal rate, tool wear ratio, and machining stability. Three different electrodes were used for the tool electrode fabrication including a stationary block, a rotating disk, and a running wire. The micro-EDM experiments determined that machining depth increases as feed rate decreases. Lim et al. also found that for micro-EDM of aluminum, the polarity has to be at the cathode so that an insulating layer does not form on the workpiece. In order to prevent tool deflection, it is also necessary to conduct machining in an upward path. It was reported that

during micro-EDM of aluminum, there is a formation of thin oxide layer due to the oxidation of aluminum. It is difficult for the microelectrodes to break that insulating film, so the machining does not continue. In order to solve the issues, the polarity of aluminum workpiece in micro-EDM must be set as cathode, as shown in Fig. 19.^[67]

Two of the most critical performance parameters for micro-EDM are machining time and electrode wear, as they are heavily influenced by machining parameters. Zhang et al.^[68] generated a model to determine the effect of micro-EDM process parameters on the machining time and electrode wear. The experiments utilized aluminum as a workpiece, with brass as the tool electrode and kerosene as the dielectric. Zhang et al. concluded that using the optimized conditions could result in a shorter machining time and maintain smaller electrode wear.

Several studies have been conducted on the surface finish generated during micro-EDM. Lin et al.^[69] experimented with micro-EDM alongside ultrasonic machining (USM) in an effort to create a new machined surface layer. An Al–Zn–Mg alloy was used as the workpiece material with electrolytic copper as the electrode material. Silicon carbide (SiC) abrasive particles were added for solid solution strengthening for the new layer. The results illustrated that the surface was coarser when machined by negative polarity than by positive polarity due to the energy differences, showing that positive polarity was more beneficial. The SiC was transferred to the machined surface and created a hardened layer after micro-EDM. The use of both EDM and USM resulted in an improved wear resistance and eliminated the soft layer of aluminum alloy by just using EDM. The development of a white layer on the surface of materials machined with EDM is caused by various machining parameters. Arooj et al.^[70] studied the effect of varying the electric current during micro-EDM to determine what impact it would have on the surface finish and globule formation on the material. Aluminum 6061 T6 was chosen as the material, and a cylindrical copper electrode tool was paired with kerosene oil to complete the experimental setup. EDM was conducted while changing the current and voltage, and the results were observed. Arooj et al. concluded that as the current increased, the material removal rate, average globule diameter, and inter-globule distance also increased. It was also observed that there existed a critical thickness at which the white layer would disintegrate at specific machining conditions. It was found that the surface defects increased when the current was increased in EDM.

The incorporation of materials that exhibit ultrafine grains was studied by Rosochowski et al.^[71] in relation to micro-EDM applications and improved the surface finish. Plastic deformation was used to nanostructure two different aluminum materials, Al 5083 and Al 1070, to produce a smaller grain size. A tungsten carbide tool was used for machining with an oil dielectric. Rosochowski et al. found that the use of finer grains in the materials led to a decrease in surface roughness, though it was noted that more tests

were needed to determine the optimization of parameters. However, it was clear from their study that ultrafine grain materials were influenced by the machining conditions of micro-EDM.

Micro-EDM can be one of the methods to remove burrs present in a machined surface that result from conventional machining techniques. Jeong et al.^[72] experimented with micro-EDM as a burr removal method due to its low discharge energy and small tool size. Micro-EDM machining was conducted on three materials, namely, aluminum, copper, and steel, using a cylindrical tungsten carbide tool. Jeong et al. found that the spark gap provided sufficient control of machining range, which allowed for removal of the burrs near the tool with limited damage. This process also allowed for machining of small features and reducing the issues with micro deburring. Figure 20 shows the rough, finish, and edge deburring of aluminum burrs using the micro-EDM process.^[72] The study proves that micro-EDM can be used as a postprocessing technique for removing the burrs generally formed during the milling or micro milling process.

Micro-WEDM is another major type of EDM at micro scale. There have been several studies on the micro-WEDM of aluminum alloys. Somashekhar et al.^[73] completed micro-WEDM experiments on aluminum to assess the effects of machining parameters. A model was first developed to predict the overall performance of the machining based on the material removal rate, overcut, and surface roughness. A zinc-coated brass wire was chosen as the tool electrode, and an EDM synthetic oil was used as the dielectric fluid. Somashekhar et al. concluded that the capacitance had the largest effect on micro-EDM performance, as higher values resulted in higher material removal rate and wall surface roughness. Discharge influenced the overcut of the specimens, while an increase in

feed rate led to higher material removal rates and overcuts. Accuracy and efficiency also improved when lower discharge energies were produced during machining. It was also found that erosion efficiency, melting and boiling points, and heat capacity all influenced the material removal rate. Overall, the model developed for parameter predictions proved valid and aided in determining the optimal machining conditions. Rao et al.^[74] used the Taguchi method in the WEDM of Al 2024-T6 to evaluate the influence of parameters on surface roughness and material removal rate. Deionized water was selected as the dielectric fluid, and a zinc-coated brass wire served as the electrode. The surface roughness and material removal rate were optimized using mathematical models and confirmed with the experiments. Both parameters were heavily influenced by pulse-on time, peak current, and spark gap voltage. Surface roughness was also impacted by wire tension, whereas pulse-off time and servo feed rate determined the material removal rate. Rao et al. concluded that in order to improve the surface quality, it is necessary to decrease the cutting speed. Bobbili et al.^[75] also utilized the Taguchi method along with grey relational analysis to determine the most significant variables in WEDM. For the experiments, a ballistic grade aluminum alloy was used and four variables were observed, including pulse-on time, pulse-off time, peak current, and spark voltage. The machining performance was evaluated by the material removal rate, surface roughness, and gap current of the micro-EDM process. Bobbili et al. concluded that the modeling techniques provided optimization of machining parameters and confirmed that the material removal rate, surface roughness, and gap current were improved by optimizing the parameters using the grey relational analysis.

Dry EDM is another type of the micro-EDM process where the machining operation is carried out with oxygen,

Fig. 20 (a) Rough, (b) finish, and (c) edge deburring in aluminum using the micro-EDM process

Source: From Jeong, HanYoo, Lee, Min, Cho, and Lee.^[72] ©2009 Elsevier, All rights reserved.

air, or other gas as dielectric fluid. Chen et al.^[76] used dry EDM as a coating process on aluminum with the aid of a titanium powder compact electrode. For these experiments, nitrogen gas was used as the dielectric, and the TiN coating was used to improve the corrosion resistance. Chen et al. concluded that using titanium powder compact electrode in the nitrogen dry EDM is successful in creating a TiN ceramic film on the machined surface. The quality of the surface was found to be unstable at higher electrical discharge energy. It was also found that the more the discharge energy, the coarser the TiN film will be and defects will appear due to the difference in thermal expansion between the Al and TiN matrices.

Although there have been several studies on various forms of micro-EDM of aluminum alloys, most of the studies are experimental with very few studies focusing on the modeling and simulations. The aluminum alloys usually have good machinability using conventional micromachining processes. Yet, the major benefit of micro-EDM of aluminum alloys is the generation of micro-features with fewer burrs. In addition, micro-EDM allows fabrication of parts with thin walls and intricate features because of negligible cutting forces during machining. However, very few of the above research studies focused on the fabrication of intricate shapes in aluminum alloys using micro-EDM. Therefore, future research should focus on the application

of micro-EDM in the fabrication of complex micro-features that are difficult to machine in aluminum alloys using conventional micromachining processes.

Aluminum-Based MMCs

Aluminum MMCs are mostly the aluminum alloys with reinforcement of other materials to improve the physical and mechanical properties of the alloy. As MMCs are comparatively difficult to machine using conventional micromachining processes, micro-EDM, and other non-conventional machining processes are being increasingly approached for machining this material at micro scale. There have been several research studies on the micro-EDM of various MMCs based on aluminum. A number of studies focused on investigating the effect of operating parameters on the machining performance during micro-EDM of aluminum MMCs. Dhar et al.^[77] conducted EDM machining experiments on an Al-4Cu-6Si alloy-10wt.% SiCp composite using a brass electrode at various conditions. A mathematical model was created to relate the parameters and variables of machining during micro-EDM with the aluminum alloy. The material removal rate, tool wear rate, and radial overcut were then determined. Dhar et al. concluded that the model could be used to determine the optimum machining parameters. Mohan et al.^[78]

studied the effect of utilizing a rotary electrode in hopes of a higher material removal rate, less wear, and an improved surface finish. Copper and brass electrodes were used as the electrodes, and kerosene was used as the dielectric fluid. An aluminum alloy with SiC particle reinforcements was used as a workpiece. It was found that the material removal rate increased with positive polarity electrodes as well as increased currents. On the other hand, the material removal rate decreased with an increase in pulse duration and amount of SiC. Mohan et al. also observed that the rotary electrode increased the material removal rate, and the surface roughness improved with decreased pulse currents and increased with SiC reinforcement. It was concluded that less tool wear resulted from negative polarity electrodes and lower amounts of SiC but increased with an increased current.

In another similar study, Mohan et al.^[79] conducted experiments with a rotary EDM and a hollow tube electrode to machine micro-holes in Al-SiC MMC. Brass was used for the hollow tube electrode, and kerosene was used as the dielectric fluid. Discharge current, polarity, volume of SiC, pulse duration, and hole diameter were varied in each experiment. Experiments proved that the material removal rate increased when using the rotary tube electrode as a positive polarity electrode. The wear rate of the electrode decreased and the surface roughness increased with higher pulse durations. Mohan et al. concluded that the surface roughness increased with positive polarity electrodes and higher discharge currents, whereas more SiC improved the surface roughness. Overall, the rotary tube electrode helped remove the material more effectively providing improved surface finish.

Singh et al.^[80] studied the effect of various parameters on micro-EDM of an aluminum alloy MMC. A brass tool was used for micro-EDM drilling, and kerosene was used as the dielectric fluid. Experiments were conducted by varying the parameters, and each factor was evaluated based on its effect on the workpiece. The material removal rate, surface roughness value, and tool wear increased when the current and pulse-on time increased. Surface roughness also increased with longer pulse durations.

In regard to the flush rate of the dielectric fluid, Singh et al. found that low velocities resulted in an increase in material removal rate. Figure 21 shows the SEM image of the micro-hole machined in Al-10wt.% SiCp MMC using micro-EDM, and the recast layer detail at the rim of the micro-hole.^[80]

Kathiresan et al.^[81] studied EDM machining with a die-casted aluminum alloy with silicon carbide particles that was mixed by vortex. Copper was used as the tool electrode material, and the material removal rate and surface roughness were determined. The experiments concluded that the material removal rate increased when the current increased and the weight percentage of silicon carbide was lower. It was also found that the surface roughness value decreased when the current decreased and the weight percentage of silicon carbide increased. Yan et al.^[82] conducted rotary EDM with Al₂O₃/Al 6061 in order to study the effects of various cutting parameters while using a dislike electrode. Variables included electrical and non-electrical parameters, and material removal rate, electrode wear rate, and surface roughness were observed. Copper was chosen as the dislike electrode material, and kerosene was used as the dielectric fluid. Yan et al. concluded that the electrical characteristics had a bigger effect on the machining, and the use of the dislike electrode led to higher material removal rate and electrode wear rate.

Ponappa et al.^[83] conducted EDM experiments in an effort to determine the effects of various parameters on the quality of a drilled hole. The electrode consisted of a rotary brass hollow tube and deionized water served as the dielectric fluid. Holes were drilled into magnesium nano-alumina composites, and the surface roughness and taper were observed. Ponappa et al. were able to formulate a model to represent the influence on pulse-on and off time, voltage gap, and servo speed. The experiments confirmed that taper and surface roughness largely depended on the pulse-on time as well as the servo speed. Overall, it was illustrated that the EDM method successfully drilled holes in nano-alumina composites, and the surface quality was improved when the conditions were optimized. Puhani et al.^[84] conducted EDM on aluminum silicon carbide

Fig. 21 SEM image of (a) the micro-hole machined in Al-10%SiCp MMC using micro-EDM, (b) recast layer with micro-cracks, and (c) magnified image of the recast layer

composites in an effort to evaluate the influence of various parameters. These parameters included machining parameters such as discharge current, pulse duration, duty cycle, and flushing pressure, as well as material parameters such as weight fraction of silicon carbide and mesh size. Powder metallurgy was used for the composites, and EDM was performed using EDM oil as the dielectric fluid along with a cylindrical copper tool as the tool electrode. Puhan et al. concluded that as the weight percentage of silicon carbide and mesh size increased, the hardness of the material increased while the conductivity decreased. The machining parameters found to have a large impact on the multiperformance characteristic and optimization of these conditions were calculated.

Gopalakannan et al.^[85] experimented with the EDM of an aluminum metal matrix nanocomposite that was fabricated with uniformly distributed B4C nanoparticles for reinforcement. The goal of the test was to determine the most beneficial combination of machine conditions based on the metal matrix nanocomposite and the impact of the nanoparticles. The material was machined with a copper electrode and the results were reported. It was found that the material removal rate increases, then decreases, with an increase in pulse-on time. Gopalakannan et al. also concluded that the electrode wear value decreased with higher pulse-off times. Surface roughness was found to increase when pulse current and pulse-on time increased. In another study, Gopalakannan et al.^[86] conducted EDM experiments with a copper electrode in order to analyze the machining conditions that mostly affect the material removal rate, electrode wear rate, and surface roughness. A metal matrix nano-composite of Al 7075 was fabricated and then reinforced with SiC nano-particles in preparation for EDM. Kerosene was used as the dielectric fluid and the experimental results were then observed. Gopalakannan et al. concluded that the addition of uniformly distributed nano-particles improved the results overall. It was also found that the material removal rate increased, then decreased as the pulse-on time increased and the electrode wear rate decreased with higher pulse-off times. The surface roughness value increased when the pulse current and pulse-on time increased as well.

Tak et al.^[87] experimented with micro-EDM of alumina reinforced with carbon nanotubes in varying concentrations to study their effect on the machining process. A tungsten carbide tool was used for machining the material along with EDM fluids for the dielectric fluid. Holes were machined with EDM and the results were analyzed. Tak et al. concluded that the more carbon nanotubes in the material, the higher the electrical conductivity and machining time. It was also observed that the large amount of carbon nanotubes led to sparking and a decrease in surface accuracy. Overall, the addition of carbon nanotubes in the alumina resulted in an improved dimensional accuracy because of the uniform distribution throughout the matrix.

Patel et al.^[88] conducted micro-EDM using a rotary tube electrode made of brass wire and deionized water as the dielectric material. The experiments concluded that the material removal rate increased with servo speed and pulse-on time, whereas it decreased when the pulse-off time and sparking gap voltage increased. Patel et al. also found that the electrode wear rate increased with servo speed and pulse-on time and decreased when the sparking gap voltage increased. Lastly, when the pulse-on time and servo speed increased, the hole taper increased, but it decreased when the pulse-off time and sparking gap voltage increased. The weight percentage of SiC determines the material removal rate, electrode wear rate, and hole taper, which all indicate machining success.

Powder-mixed micro-EDM is one of the recent innovations for the enhancement of capabilities of micro-EDM process. In recent years, to improve the quality of the machined surface and to reduce the surface defects, powder-mixed micro-EDM process was found to be effective. In this hybrid process, the electrically conductive powder is mixed in the dielectric, which reduces the insulating strength of the dielectric fluid and increases the spark gap between the tool and the workpiece. The surface properties of both conventional EDM and powder-mixed EDM were evaluated in terms of surface micro-topography, elements, and wear resistance. Hu et al.^[89] used a SiC particle-reinforced aluminum matrix composite as the material with a copper electrode. Overall, the experiments conducted illustrated that powder-mixed EDM resulted in improved surface properties. Hu et al. stated that the roughness decreased and the concentrations of Si and C increased. Using powder-mixed EDM also increased the hardness of the material as well as the corrosion and wear resistance. By comparing conventional EDM with powder-mixed EDM, Hu et al. determined that powder-mixed EDM has great potential for applications in MMC machining. Figure 22 shows the comparison of the machined surface using conventional EDM and powder-mixed EDM.^[89] It was found that powder-mixed EDM produced comparative shallower crater height in addition to lesser carbon deposition, which provided smoother surface finish.

Fig. 22 SEM image of the machined surface by (a) conventional EDM and (b) powder-mixed EDM

Source: From Hu, Cao, Song, Hou, Zhang, Chen, and Wei.^[89] ©2013 Elsevier, All rights reserved.

While prevalent, EDM of MMC machining is limiting due to its low material removal rate and high surface roughness. The potential for adding aluminum powder in kerosene dielectric is examined through experiments conducted by Talla et al.^[90] A die-sinking EDM setup was used for the machining along with a copper electrode, and aluminum and alumina powders were added to the specimens. The powder concentration, peak current, pulse on time, and duty cycle were all observed in relation to their effect on material removal rate and surface roughness value. Talla et al. concluded that powder-mixed electric discharge machining not only increased productivity but also improved surface quality. Material removal rate improved and the surface roughness value decreased, and the thermal conductivity, coefficient of thermal expansion, and density also affected both indicators.

Micro-WEDM is another effective process of machining aluminum MMCs with high complexity, dimensional accuracy, and surface finish. There have been several research studies on investigating the feasibility of machining various aluminum MMCs using micro-WEDM. Sivaprakasam et al.^[91] conducted micro-WEDM of A413-B₄C MMC in an effort to analyze the machining characteristics and their effect on machining performance. The RSM was used to model the effect of machining conditions, including voltage, capacitance, and feed rate on the material removal rate, kerf width, and surface roughness. Sivaprakasam et al. concluded that the mathematical analysis provided sufficient evidence of the most influential parameters and predicted the values for optimal material removal rate, kerf width, and surface roughness. Rozenek et al.^[92] conducted WEDM with a negatively polarized brass wire tool for machining two different aluminum alloy materials. The tests concluded that an increase in current and pulse-on time resulted in an increase in discharge energy. As the current, voltage, and wire feed rate increased, the surface roughness increased as well. Due to the abrasive particles that are used to reinforce MMCs, machining caused severe tool wear and subsurface damages. Micro-WEDM is a viable option for machining MMCs, but it is dependent on several factors including discharge current, pulse time, and voltage. Bobbili et al.^[93] conducted WEDM tests on both aluminum alloys 7017 and rolled homogeneous steel in order to study the conditions affecting material removal rate and surface roughness. Before the experiments were completed, a model was created for the input variables, including pulse-on time, flushing pressure, input power, thermal diffusivity, and latent heat of vaporization. Bobbili et al. concluded that the predictions from the mathematical model were consistent with the data from the micro-WEDM tests. It was also determined that the material removal rate increased for materials with low melting temperatures and specific heat. Lastly, the experiments revealed that the formation of defects on the surface increased with higher currents and pulse-on

times, whereas the wear rate of the brass wire increased when the input energy increased, leading to wire damage.

The micro-EDM process can be a very useful micro-machining technique for successful machining of aluminum MMCs. The aluminum MMCs are hard to machine using conventional turning, milling, and drilling processes because of the hard reinforcement particles. There have been a significant number of studies on micro-EDM of aluminum MMCs with SiC, Al₂O₃, and B₄C reinforcement. A variety of EDM processes, i.e., micro-EDM drilling, micro-WEDM, and powder-mixed micro-EDM, have been employed for the machining of aluminum MMCs. The effect of various parameters on the micro-EDM performance of MMCs has been established from the experimental studies. However, very few studies have focused on modeling and simulation of the material removal mechanism during micro-EDM of MMCs.

Aluminum-Based Ceramics

Micro-EDM is advantageous for machining of alumina-based ceramics, because the machining can be completed irrespective of the physical properties of the material such as strength and hardness, as long as the material is electrically conductive. Micro-EDM is dependent on various machining parameters including, but not limited to, pulse energy, voltage, current, electrode polarity, electrode shape, dielectric liquid, pulse duration, pulse interval, duty ratio, and so on. Zhang et al.^[94] experimented with an aluminum oxide-based ceramic and a tool electrode made from red copper. The tests showed that the diameter of discharge point, material removal rate, and surface roughness all increased when the discharge current and pulse-on time increased. Zhang et al. concluded that micro-EDM is possible with conductive ceramics under specific machining conditions. Lin et al.^[95] conducted micro-EDM on a conductive aluminum ceramic with kerosene and copper electrode based on the Taguchi model of experimental design. The experiments resulted in an increase in material removal rate when peak current and pulse durations were increased due to the increased discharge energy. Electrode wear rate was found to increase with peak current, whereas it decreased with pulse duration. Lin et al. also found that surface roughness increased with pulse duration and peak current as material removal effects became more pronounced. Machining parameters were optimized to positively impact the material removal rate, electrode wear rate, and surface roughness based on the experimental data.

Both the studies by Zhang et al.^[94] and Lin et al.^[95] showed the applicability of micro-EDM process for conductive ceramics. However, alumina ceramics have very low thermal conductivity, and hence are difficult to machine using micro-EDM process. The quality of the micro-features could also suffer. The electrode wear rate is also found to be higher for micro-EDM of ceramics. One

possible way to improve the machinability of conductive ceramics in micro-EDM is to further increase the electrical conductivity of the ceramics. This can be done in many ways, including applying coating layer of highly conductive materials on the alumina surface before machining using micro-EDM.

Micro-Electrochemical Machining of Aluminum Alloys

Electrochemical machining (ECM) is based on a controlled anodic electrochemical dissolution process of the workpiece (anode) with the tool (cathode) in an electrolytic cell, during an electrolysis process. Micro-ECM utilizes very small interelectrode gaps ($<20\text{ }\mu\text{m}$) in order to obtain the required accuracies.^[96] Micro-ECM can produce almost all the shapes produced by the micro-EDM process; however, the difference is that micro-ECM produces parts with improved surface finish at the expense of machining speed. Therefore, the micro-ECM process is mostly used in applications where surface finish and dimensional accuracy are of prime importance.

There have been very few works on the micromachining of aluminum and its alloys. Dharmalingam et al.^[96] studied the stability and economical productivity of micro-ECM by observing the process parameters associated with micro-ECM. Machining voltage, electrolyte concentration, and frequency were analyzed in terms of the overcut and material removal rate. Drilling was completed on Al-SiCp using micro-ECM along with the Taguchi method and variance analysis. The experiments determined the optimum parameter settings for the process operation that correlated to the predicted settings from the developed model, with frequency having the largest impact on material removal rate. Sankar et al.^[97] conducted ECM on aluminum metal matrix reinforced with boron carbide (B_4C) to study the effects of the reinforcement particles. Fine abrasive particles mixed with the electrolyte increased the material removal rate along with the surface quality of the machined material. Sankar et al. concluded that the addition of boron carbide and graphite deterred anodic dissolution progression, and it was eliminated by adding a SiC abrasive medium in the flow path of the electrolyte. Overall, this change improved the performance of the machining process and that the abrasive ECM was more successful than the traditional ECM. The higher material removal rate and lower surface roughness seen in the experiments further support this claim. Figure 23 shows two applications of micro-ECM of aluminum MMCs. Figure 23a shows an optical image of a micro-hole machined on Al-10 wt.% SiCp at a parametric combination of 7 V, 30 g/L, and 50 Hz.^[96] The SEM image of aluminum metal matrix reinforced with boron carbide (B_4C) machined with abrasive ECM is shown in Fig. 23b.^[97] Although micro-ECM can successfully machine aluminum MMCs, the material removal rate is very low in the micro-ECM process compared to the micro-EDM and laser

Fig. 23 (a) Optical image of a micro-hole machined on Al-10 wt.% SiCp at a parametric combination of 7 V, 30 g/L, and 50 Hz;^[96] (b) SEM image of aluminum metal matrix reinforced with boron carbide (B_4C) machined with abrasive ECM

micromachining processes. In addition, the micro-features obtained by the above studies are not very convincing. The parameters should be optimized as well as better gap control system should be implemented to enhance the quality of the micro-features obtained by micro-ECM.

Laser Micromachining of Aluminum Alloys

Laser micromachining has been found to be one of the most widely used micro manufacturing processes for machining aluminum alloys and alumina ceramics. The laser has been used for a variety of micromachining processes including laser micro-drilling, laser micro-turning, laser micro-milling, and so on. In recent years, laser milling of industrial materials such as aluminum, steel, titanium, and ceramics is of significant commercial interests in mold and die, automotive, and aerospace industries. Figure 24 shows the simple schematic representing the basic mechanism of the material removal in laser micromachining.^[98] In laser micromachining, a beam of laser generated from the system is focused onto the target workpiece surface by the use of converging lens. The absorbed energy from the laser pulses are used to melt the target material and raise the temperature of the material at which the atoms gain sufficient energy to enter into a gaseous state. The material is removed mostly in the form of melting and evaporation. The molten metal is partly removed by the evaporation and plasma pressure, and the rest of the materials remain on the machined surface and edges. As shown in Fig. 24, there is always a heat-affected zone underneath the machined surface for laser micromachining.

One important advantage of laser micromachining is that the laser beam can be used for a number of machining operations including micro-drilling, micro-milling, micro-turning, and even micro-texturing. Laser ablation is often used for the machining of microsystem devices due to the fact that it allows for difficult-to-cut materials to be machined. Some of these materials include hardened steel, carbide, titanium alloys, and ceramics. Laser micromachining for roughing along with high-speed milling for finishing was completed to determine the surface quality of the finished product.^[98] Quintana et al. conducted

Fig. 24 Schematic representation of the basic mechanism of laser micromachining and machined surface

Source: From Quintana, Etxarri, Sanz, Aranzabe.^[98] ©2008 Open Source.

these tests with a focus on the laser power, frequency, and velocity, and their impact on the geometric precision of the features. It was concluded that laser machining could successfully generate molds in materials that are typically hard to machine. The experiments also determined that milling and laser machining are both beneficial when machining complex geometries on the specimen. Laser micro-drilling allowed for precise, small holes and that the trepanning mode is the optimal mode for the process. Lastly, it was found that laser texturing could be used to generate high-precision dimples, whereas laser micro-machining proved useful for microstructuring. Figure 25 shows the image of embossing die and micro-hole that were machined successfully in aluminum AS9G alloy using pulsed laser micromachining.^[98]

One of the challenges of laser micromachining of aluminum is the high reflectivity of aluminum to laser radiation. In order to solve this issue, an adapted method of laser machining was developed. Tunna et al.^[99] conducted laser micromachining by using shorter wavelengths that resulted in a lower reflectivity as well as decreased the obtainable geometry dimensions. The machining was carried out using the Nd:YAG laser. The machining rate was calculated by using the amount of pulses necessary for proper drilling of the material. It was concluded that the incident wavelength,

Fig. 25 (a) Embossing die and (b) micro-hole created by micro-second laser on aluminum AS9G

Source: From Quintana, Etxarri, Sanz, Aranzabe.^[98] ©2008 Open Source.

processing fluence, and plasma generation all had a significant influence on the average machining depth. Increasing the wavelength greatly reduced the machining depth. However, the machined micro-holes were found to be tapered from the entrance to exit. Mishra and Yadava^[100] developed a model to predict laser beam percussion drilling in order to predict the hole taper and material removal rate during micromachining of aluminum. The methods by which the model was developed included finite-element method and artificial neural network. Thermal models were developed for laser micromachining based on the thermal properties dependent on the temperature, optical properties, and phase changes. Tests were conducted to support the model for laser micromachining of aluminum. Micro-holes were drilled into aluminum sheets normal to the surface and the results were observed. The authors concluded that the hole taper decreased when the pulse width, pulse frequency, peak power, and workpiece thickness increased. It was also found that increased laser parameters such as pulse width, pulse frequency, and peak power led to increased material removal rates. It was determined that the machining parameters could be accurately predicted for laser beam drilling.

Krstulovic et al.^[101] studied the effect of laser micro drilling in pulsed laser ablation of aluminum in water and in air with a Nd:YAG laser under high energies. The laser micromachining was evaluated based on the volumes of the produced craters in relation to the water layer thickness. The drilling of aluminum samples was completed under water and in air, and the dimensions of the craters were measured. The authors concluded from the tests that wet ablation drilling resulted in enhanced depth and volume compared to dry drilling. The quality of the crater shape and drilling rate also improved when the water layer thickness was varied. It was also found that rippling and rough dendritic structure existed on the crater surface and were better than dry conditions in terms of surface quality. Overall, underwater laser drilling proved to provide fast micro-drilling with improved resolution, quality, and efficiency.

In another similar study, laser microdrilling was carried out to create micro-holes in various materials using 60-fs Ti:sapphire laser pulses.^[102] The influence of various operating parameters and material properties was studied for laser micromachining of Al, Mo, Ti, Cu, Ag, Au, and brass in air. During the machining, each pulse removed a small amount of material, and the results were collected for further evaluation. It was concluded from the tests that there was a significant difference in the physical material removal process in femtosecond laser machining compared to picosecond and nanosecond laser micromachining. It was seen that there was a solid-to-vapor transition during femtosecond laser micromachining, and that this type of machining is beneficial for machining hard materials and generating deep micro-holes. It was determined that femtosecond laser machining is most applicable for micron-scale

material removal in the absence of liquid-phase contamination. Figure 26 shows the arrays of 1.5 μm diameter micro-holes machined in Al foil by femtosecond laser micromachining.^[102]

There have been a number of studies on laser micro-milling and micro-structuring of aluminum and its alloys. Williams et al.^[103] investigated the use of pulsed ytterbium-doped fiber lasers in laser milling due to its low-cost and flexible process parameters. This new method of laser milling expands the processing window by allowing the pulse duration, shape, and repetition rate to be changed based on the desired outcome. Aluminum was selected as the material for testing, and the factors that influenced surface roughness and material removal rate were analyzed to determine the operational success. These conditions included repetition frequency, pulse overlap, scanning strategy, and track distance. Williams et al. concluded that the frequency with the highest pulse energy and longer pulse durations resulted in the highest material removal rate. In regard to surface roughness, the optimal pulse frequencies led to higher surface roughness values. It was also found that shorter pulse durations led to lower surface roughness values. Lastly, Williams et al. determined the optimal track displacement and pulse overlap to achieve the desirable surface roughness and material removal rate.

Dhupal et al.^[104] investigated the micro-milling performance of aluminum titanate (Al_2TiO_5) using pulsed Nd:YAG laser. The thermal properties of Al_2TiO_5 ceramic allow for its application in the automobile and aerospace industries. The authors used laser micromachining to carry out micro-grooving in Al_2TiO_5 ceramic as well as to evaluate the effect of different process conditions on the micro-grooves. The parameters of focus included current, pulse frequency, pulse width, assist air pressure, and cutter speed. These conditions were analyzed based on their impact on the taper and depth deviation of the micro-grooved aluminum specimen. It was concluded that the process parameters need to be optimized and controlled in terms of taper angle and depth deviation. The authors

found that the taper angle deviation decreased first, then increased with the lamp current, and at medium lamp current values, it decreased with a decrease in pulse width. It was also concluded that lower cutting speeds allowed for smaller taper angle and depth deviations. The tests determined that medium pressure air assist values were necessary for low deviation of depth and taper medium values of assist air pressure. The authors identified the optimal setting of parameter that provided least variation in the depth and taper angle and improved the surface finish around the edges of the micro-grooves. Figure 27 shows the SEM micrographs of the micro-grooves machined using an optimal parameter setting.^[104]

Perrie et al.^[105] conducted micro-structuring in aluminum under the helium stream flow using femtosecond and nanosecond laser pulses (180 fs, 775 nm laser pulses). Rolled aluminum was used as the material, and the machining results were analyzed for material redeposition, ablation rate, and residual surface roughness. The effect of various process settings including fluence and energy density on material redeposition, ablation rate, and residual surface roughness in laser micro-machining has been evaluated. The tests proved that the addition of helium reduced the negative effects of surface oxidation and redeposition of debris as gas breakdown is avoided. It was found that there existed residual thermal effects, debris formation, and a poor surface finish when using the average power density and a higher fluence. On the other hand, a low fluence level and power density resulted in an improved surface with limited melt. Figure 28a shows a square micro-structure machined using laser ablation micro-milling process. Figure 28b shows the magnified image of the ablated surface, and Fig. 28c indicates the debris deposited on the ablated surface.^[105]

In a similar study, Wu et al.^[106] conducted femtosecond pulse laser ablation tests on aluminum at various ambient air pressures to evaluate their effect on the process. The shadowgraphic method was used to observe the effects of different ambient air pressures after aluminum samples were machined. Wu et al. concluded that the ambient air

pressure had a large impact on the laser machining. Specifically, ambient air pressure directly affected the formation of concentric and semicircular stripes, dense target material ejection, shock wave, and contact front. It was also found that the addition of a high vacuum condition could also generate a stripe pattern when the target is ablated by a large pre-pulse or preceding pedestal. The stripe pattern was found to be due to the ionized ambient air and ablated target material and related directly to the air pressure behind the shock wave front. A spear-like ejection pattern of the material was seen as a result of longer time delays, and the ambient air pressure was confirmed to aid in dispersing the laser energy in the target.

Perrie et al.^[107] also investigated the feasibility of micro-structuring in alumina (Al_2O_3) ceramic using the femtosecond laser ablation process. The micromachining of alumina ceramic in air was evaluated by conducting femtosecond laser micro-structuring to optimize the processing conditions. The processing conditions were judged based on their impact on residual surface features, ablation rate, and residual surface roughness. Perrie et al. concluded from the experiments that using femtosecond optical pulses resulted in advantageous edge quality at low scanning intensities. There was also no discoloration on the surface of the specimen. It was found that the surface roughness could be lowered by using a specific pulse fluence value based on the testing data. Perrie et al. also stated that a thick remelted layer existed on the surface due to the alumina processing. The values for the ablation threshold was determined, and it was concluded that material redeposition, surface roughness, and residual thermal effects were lowered when a low scanned intensity was used.

Kruger et al.^[108] conducted femtosecond pulse laser ablation on aluminum alloys and evaluated the anodic oxide coatings that were detected by acoustic observation. Ablation experiments were completed, and the interaction between the laser pulse and the target was investigated. The ablation craters were measured microscopically, and the experimental data were analyzed. It was found that the ablation thresholds for the oxides were higher than those for the aluminum. Kruger et al. concluded that the crater geometry was supported by the evaluations from the online

acoustic observations. It was evident from the experiments that there exists a linear relationship between the acoustic signal and the laser fluence above the ablation threshold. Lastly, it was stated that femtosecond laser machining is more applicable in hard materials compared to those with low melting points such as aluminum.

In another study, Valette et al.^[109] analyzed the mechanical and thermal effects from femtosecond laser pulse machining on aluminum single crystal. The crystallinity and mechanical contributions were compared after the tests were completed. Two different scanning speeds were used for the experiments, and the crystallographic orientation distribution function and micro-stresses and mechanical effects were analyzed. It was found that the surface finish was relatively smoother at a higher scanning speed. The recrystallization around the initial crystallographic positioning of the single crystal determined the thermal response. It was seen that there was an increased dislocation density near the sample subsurface, identified by the diffraction peak broadening. Lastly, the thermal effects were more influenced by the number of pulses compared to the mechanical components, though both effects occurred at a specific depth below the specimen surface.

Recently, laser micromachining was used in micro-turning applications for machining the cylindrical shaped materials. The working principle is the same as that of other laser micromachining processes, where a cylindrical rotating workpiece is used instead of flat surfaces. Figure 29 demonstrates the schematic representation of the laser micro-turning process.^[110] There have been several studies reported by Kibria et al. on microscale turning of alumina ceramic. Nd:YAG laser micro-turning was completed on cylindrical ceramic materials in an effort to study the laser output responses.^[110] These responses include depth of cut and surface roughness, which are dependent on lamp current, pulse frequency, and laser beam scanning speed. Micro-turning tests were done on cylindrical aluminum oxide using a single laser beam with predetermined settings from trial experiments. Kibria et al. concluded that by controlling the lamp current, pulse frequency, and laser scanning speed, while changing the percentage of overlapping laser spots, it was possible to generate a specific depth

Fig. 29 Schematic diagram of the laser micro-turning process
Source: From Kibria, Doloi, and Bhattacharyya.^[110] ©2010 Springer, All rights reserved.

after turning with a quality surface finish. It was found that lamp current and scanning speed have a large effect on the depth of cut, whereas pulse frequency had a moderate impact on the depth of cut. Lastly, as the scanning speed increased, the surface roughness increased, whereas the surface roughness decreased with higher lamp currents and pulse frequency, as shown in Fig 30.^[110]

Kibria et al.^[111] studied the various parameters associated with Nd:YAG laser micro-turning after developing an experimental design using the Taguchi methodology. Laser beam average power, pulse frequency, workpiece rotational speed, and Y feed rate were all considered. The surface roughness and micro-turning depth deviation were selected as the criteria for determining the success of the tests. Alumina was the material, and micro-turning was completed using a holding and rotating fixture for alumina workpiece.

It was found that the factors with the largest effect on the surface roughness were laser beam average power and Y feed rate, and that the depth deviation was most impacted by the laser pulse frequency and Y feed rate. The optimal parameter settings for laser micro-turning were identified based on the Taguchi analysis and were confirmed by the experimental testing. Laser micro-turning with dimensional accuracy on cylindrical workpieces was investigated in order to determine how processing parameters impact the overall surface roughness and micro-turning depth deviation.^[112] Laser micro-turning experiments were completed on aluminum oxide, and the surface roughness and depth deviation were analyzed. The authors were able to develop models based on the impact of process parameters on the workpiece and identified the optimum parametric combination to achieve the least surface roughness and desired depth. The model was verified from the laser micro-turning, and it was evident that the surface roughness decreased with more laser scan passes, whereas the depth deviation increased.

Laser turning was completed on a ceramic material in order to create micro-grooves on the specimen. Dhupal et al.^[113] developed a work-holding device based on a microprocessor that would allow for rotational movement necessary for turning. Aluminum oxide ceramic was chosen as the workpiece, and micro-turning operations were conducted based on empirical models. Factors considered in the machining included lamp current, pulse frequency, pulse width, assist air pressure, and cutting speed in relation to multi-responses of upper, lower, and depth deviation. The turning tests concluded that the lamp current directly affected the upper deviation of the laser-turned micro-groove and was lowest at a medium to a low level

Fig. 30 SEM images of the laser-turned surface on alumina-based ceramic machined at various process parametric settings
Source: From Kibria, Doloi, and Bhattacharyya.^[110] ©2010 Springer, All rights reserved.

of pulse frequency. It was also found that the lowest width deviation occurred with high lamp currents and medium pulse frequency. The minimum depth deviation was observed when a medium-level lamp current with a somewhat high pulse frequency was used. Regarding the cutting speed, higher speeds were recommended for lower upper width deviation and lower speeds were recommended for minimum lower width and depth deviation. Lower deviations were also observed when high values of air assistance were used. Figure 31 shows the optical and magnified SEM images of the micro-grooves in alumina fabricated by the laser micro-turning process.^[113]

The accuracy of laser turning, specifically with cylindrical parts, was examined through the generation of square micro-grooves in alumina ceramic.^[114] The laser micro-turning operation was heavily dependent on the process parameters associated with laser machining, including lamp current, pulse frequency, pulse width, cutting speed, and assist gas pressure. Dhupal et al. conducted experiments based on design of experiments, and the results were used to create a predictive model using feed-forward artificial neural network and RSM. It was found that laser turning could be accomplished with minimal predicted deviations with an acceptable range of error. It was determined that the optimal parameter combination was lamp current of 9 A, pulse frequency of 3.2 kHz, pulse width of 6% duty cycle, cutting speed of 22 rpm, and assist air pressure of 1.3 N/mm², which provided micro-grooves with improved surface finish and dimensional accuracy in terms of width and depth of micro-channels.

There have been a significant number of studies on the laser micromachining of aluminum alloys, aluminum MMCs, and alumina ceramics. The major advantage of laser micromachining over other conventional and nonconventional machining processes is that it can machine materials irrespective of hardness and electrical conductivity. The extensive studies demonstrated various capabilities of laser micromachining including machining of submicron holes in hard alumina ceramics. The major concern of the

laser micromachining as indicated by several studies is the formation of a heat-affected zone around the micro-features, which could impact the strength and life of the product/parts.

Abrasive Jet Machining of Aluminum Alloys

In recent years, abrasive water jet machining (AWJM) has been scaled down to machine parts at micro scale. The AWJM can be used for micro milling by using the micro-sized nozzle diameter. AWJM uses high-pressure water jet mixed with abrasive slurries or small erodent particles to remove material from a target surface. Figure 32 shows the schematic representation of the AWJM process for vertical^[115] and inclined orientation^[116] of the nozzle. Some AWJM uses compressive air to accelerate the speed of the abrasive particles. AWJM or simply abrasive jet machining can produce various types of micro features including micro-holes, micro-channels, and stepped planer areas that are used in various important applications such as flat panel displays, inertial sensors, and microelectromechanical systems (MEMSs).^[115,116]

Conducting AWJM under water can be advantageous due to the fact that it reduces noise and contains debris from the machining process. There have been several studies on the AWJM of aluminum alloys at micro scale. Haghbin et al.^[115] compared the performance of submerged and unsubmerged abrasive water jet micro-milling in effort to determine the effect on the diameter and erosion footprint. Machining was conducted on 6061-T6 aluminum and 316L stainless steel at various depths, and the channels were then observed for further evaluation. It was concluded that unsubmerged channels were wider than those machined submerged for water-only jets, entrain air jets, and entrained air and particle jets. It was also found that the centerline erosion rate and volumetric erosion rate both decreased with channel depth. Channel geometry led to the decrease in erosion rates, whereas standoff distance, jet angle, and jet direction did not have an effect. The experiments proved that that submerged abrasive water jet micro-machining is advantageous due to the fact that narrower channels can be produced, and the resolution is enhanced, whereas noise and abrasive debris are limited. It was found that the widths of the channels in water are smaller than those machined in air for both stainless steel and aluminum alloy. It was also found that the micro-channels machined at aluminum alloy are wider than those machined in stainless steel. In another study, Hangbin et al.^[117] proposed a model to predict the size and shape of the micro-channels machined in 316L stainless steel and 6061-T6 aluminum alloy based on AWJM in unsubmerged and submerged conditions. It was determined that as the channel depth increased, the erosion rate decreased. The tests also concluded that the fluid flow was limited by the channel walls due to the narrow erosive pattern from the jet footprint.

Haghighin et al. determined that the channels became wider as they were deepened by the machining.

Ally et al.^[116] conducted abrasive jet micromachining experiments on aluminum 6061-T6, Ti-6Al-4V alloy, and 316L stainless steel in order to validate the developed models and observe the effect of process parameters. For the experiments, the three materials were machined from a stage with a nozzle on a rotating mount with aluminum oxide powder. The channels that were created in the material were measured in terms of erosion rate, and the mass flow rate was calculated beforehand. The angles that created the maximum erosion rate were identified and then used in the prediction model. The model predicted both unmasked, symmetric channels machined normally and unmasked asymmetric channels in the transverse plane. The centerline depths were accurately predicted with limited error, proving that models were suitable for abrasive jet machining. It was reported that for all three materials, an inclination of the jet relative to the surface provided the best material removal rate. The peak erosion rate was obtained at 25° and 30° inclination angles of jet relative to the surface. It was concluded that abrasive jet machining was suitable for machining comparatively shallower features in aluminum alloys. Figure 33a shows the SEM image of a machined channel in 6061-T6 aluminum alloy. Figure 33b shows that some abrasive particles got embedded on the machined surface of 6061-T6 during machining. The magnified image of the machined surface is shown in Fig. 33c.^[116]

Ultrasonic Micromachining of Alumina-Based Ceramics

USM is a process of removing materials by the repeated impact of the abrasive particles between the ultrasonically vibrated tool and the stationary workpiece. In the USM process, a tool strikes the surface of the workpiece at about 30,000 times per second with fine abrasive slurry flowing through a very small gap (10–100 μm) between the tool and the workpiece.^[118] The machining happens when the abrasive slurry impacts the workpiece during the downstroke

motion of the vibrating tool causing the removal of material from the workpiece. The abrasive slurry also works as a coolant and keeps the material from becoming heated and distorted, and at the same time carries away the material to be removed. The material removal mechanism in the USM is the use of vibrating abrasive particles to create micro-cracks on a material surface and to evaporate the material with a very high frequency and low amplitude. Since the cutting forces are negligible due to very minimal/no contact between the tool and the workpiece, the USM process is applied for the microscale machining of glass, ceramics, and other brittle materials. Figure 34 shows the schematic representation of the USM process.^[118]

Lee and Kim^[118] investigated the effects of various parameters of USM, including abrasive particle and machining force, on the material removal rate and tool wear during micro USM of alumina ceramics. During the experiments, the USM process was applied for machining highly accurate micro-holes with a diameter of 27 μm and a depth of 300 μm with an aspect ratio exceeding 10. It was found that the MRR, surface finish, and tool wear depend on the grit size. The surface finish improved significantly when higher number of grit particles, i.e., smaller sizes of grit particles, were used. It was found that a smaller abrasive particle size and micro-tool feed rate could provide micro-holes with improved accuracy and good machining

Fig. 33 SEM images of (a) a masked channel in aluminum 6061-T6 after five passes of the jet at a scan speed of 0.3 mm/s and a particle velocity of 106 m/s and (b) embedded particles in a masked channel in aluminum 6061 T6 alloy after being machined with 50 μm aluminum oxide particles

performance. Figure 35 shows the SEM images of the micro-tool used in USM, and the fabricated micro-hole in the alumina ceramic.^[118] Although micro-USM can fabricate quality micro-holes in the brittle material, the fabricated micro-holes become tapered at the exit as indicated by the authors. Therefore, it is important to investigate the ways of reducing or eliminating taper and improving the accuracy in micro-USM process.

Jianxin and Taichiu^[119] investigated the properties and microstructures of different compositions of the alumina ceramics on the MRR and surface roughness during USM of alumina ceramics. The authors varied three particle-reinforced ceramics composites ($\text{Al}_2\text{O}_3/\text{TiC}$, $\text{Al}_2\text{O}_3/\text{TiB}_2$, and $\text{Al}_2\text{O}_3/(\text{Ti,W})\text{C}$), one whisker reinforced ceramic composite ($\text{Al}_2\text{O}_3/\text{SiCw}$), and one combined whiskers and particle reinforced composite ($\text{Al}_2\text{O}_3/\text{TiB}_2/\text{SiCw}$). It was found that the fracture toughness of the ceramics was the most important parameter influencing the MRR in USM of ceramics. The MRR decreased, whereas the machined surface improved with the increase of fracture toughness of the composites. It was also found that the whisker directions influenced the machining performance of the ceramic composites. Although this study determines the effect of fracture toughness on the machining performance, there could be significant influence of the reinforcement particle

properties on the machining performance which was not considered.

Kumar and Khamba^[120] investigated the mechanism and behavior of certain tool and workpiece material combination during the USM of alumina ceramics. The authors discussed the theoretical background of the experimental study and modeled the effect of process parameters on the material removal rate and depth of penetration during the USM process. It was found that the MRR increased with the increase of abrasive grain size, static load, and amplitude of the tool tip. Higher static loads resulted in a lower amplitude of vibrations with increased contact time. Lachhuanvela et al.^[121] investigated the influence of process parameters such as abrasive grit size, slurry concentration, power rating, tool feed rate, and slurry flow rate on the generated hexagonal hole profile during the USM of alumina ceramics. It was found that the profile accuracy of the job greatly depended on the size of the abrasives. It was also found that an increase in slurry concentration decreased micro-hole accuracy, and both lower and higher values of the tool feed rate as a whole reduced the profile accuracy. In addition, long duration of machining with finer grit size and higher power supply caused further taper or courser craters on the machined surface. Based on the experimental analysis, the grit number of 600, slurry concentration of 30%, power rating of 50%, and feed rate of 1.08 mm/min provided better profile accuracy during micro-USM of Al_2O_3 ceramics.

There have been several studies on the rotary ultrasonic machining (RUM) of alumina ceramics. Ahmed et al.^[122] investigated the surface and subsurface damages of alumina dental ceramic (Al_2O_3) after machined by RUM. They also compared the RUM-machined surface with that of the diamond ground surface. It was reported that smoother surface with lesser micro-cracks could be obtained in RUM compared to the diamond grinding process. Figure 36 shows the SEM images comparing the dimensional accuracy, surface finish, and subsurface cracks between the machined

Fig. 35 SEM images of (a) micro-tool used in the USM process and (b) micro-hole made by USM in Al_2O_3 ceramics (SiC#8000, 50 wt.%, depth: 300 μm , aspect ratio: 10)^[118]

surfaces obtained by diamond grinding and RUM.^[122] It can be seen from Fig. 36 that RUM produced better corner accuracy as well as smoother surface finish compared to the diamond grinding process. This study mostly presented the qualitative information on the surface and subsurface quality. The authors could provide the information about surface roughness and crack lengths to make their claim more convincing.

In another recent study, Singh and Singhal^[123] investigated the effect of various process parameters on the machining characteristics during the RUM of alumina ceramics. The authors conducted statistical analysis using RSM, design of experiment, and analysis of variance to identify the optimal parameters. It was found that with the optimized parameter setting, the material removal rate and chipping size were 0.4166 mm/s and 0.5134 mm, respectively, with a combined desirability index value of 0.849. This study reported that there was some plastic deformation causing the brittle fracture during the material removal from alumina ceramics using RUM.

CONCLUSION AND OUTLOOK

This work presents a comprehensive overview of the micromachining of aluminum alloys. A variety of micro-manufacturing processes, both conventional and nonconventional, has been used to machine aluminum alloys, aluminum MMCs, and alumina ceramics at micro

scale. This article focused on inclusion of as many research works as possible from the literature covering all aspects of the micromachining of aluminum alloys. A brief overview of each micromachining process has been included in addition to presenting the key results/findings and achievements reported by researchers in the micromachining of aluminum alloys. The following conclusions can be drawn from this article:

- The conventional micromachining processes, such as turning, milling, grinding, and drilling, have been found to be suitable for machining most of the cast and wrought aluminum alloys. However, it was found difficult to machine aluminum-based MMCs and ceramics using the conventional micromachining processes due to increased hardness and strength of those materials.
- As a result, nonconventional micromachining processes were approached to machine aluminum MMCs and alumina ceramics. Although there have been many research studies on the conventional machining of aluminum MMCs at micro scale, very few studies reported machining of alumina ceramics at micro scale using conventional processes.
- Nonconventional micromachining processes, especially micro-EDM, were found to be the most suitable processes for machining aluminum-based MMCs at micro scale. Micro-EDM drilling is able to machine high-aspect-ratio micro-holes in all kinds of aluminum alloys with high accuracy. On the other hand, micro-WEDM is capable of cutting any 3D profiles, i.e.,

Fig. 36 SEM micrographs of surface quality and edge chipping resulted from diamond grinding and RUM: (a) surface quality by diamond grinding, (b) surface quality by RUM, (c) edge chipping by diamond grinding, and (d) edge chipping by RUM^[122]

micro-gears, micro-fins, and complex micro-molds, in aluminum alloys and composites.

- Laser micro-machining was found to be the most suitable process for machining alumina-based ceramics at micro scale. Laser micromachining was used for microscale drilling, turning, milling, and even grinding for alumina-based ceramics.
- USM has been found to be capable of machining alumina ceramics at micro scale with high accuracy. Micro-features as small as 30 μm have been machined in alumina ceramics with improved accuracy and surface finish.

Although there has been a significant amount of research works on the micromachining of aluminum alloys, a number of issues remain unsolved. The following are some of the challenges and unsolved issues in the micromachining of aluminum, which should be taken care of by future researchers:

- The burr formation and unpredicted tool wear were found to be the two major concerns during conventional micromachining of aluminum alloys. Several approaches have been reported including use of another micromachining process to remove burrs from the micro-slots and machined structures. Similarly, different approaches, such as tool condition monitoring, modifying tool geometry, and providing protective coating on the cutting edges, have been discussed in the literature. However, these key issues need to be investigated further to improve the usability and product life of micro parts and components machined by conventional micromachining processes.
- There are very few studies on solving the challenges faced in conventional micromachining using hybrid processes, i.e., combining two processes in a single setup. For example, some of the aluminum MMCs and alumina ceramics could be better machined in micro-milling and micro-turning with the assistance of laser at the tool-workpiece interface.
- One of the novel ways of improving the tool life and performance of the cutting tool in turning is to create grooves or micro-holes on the rake surface of the cutting tool. Laser micromachining or micro-EDM can be used to create micro-holes or grooves on the cutting tool to improve the chip-breaking process, reduce the tool tip temperature, and improve the surface finish of the machined part. This can also be considered a hybrid micromachining process.
- One of the major challenges in the micro-EDM and laser micromachining processes is the heat-affected zone and comparatively inferior surface finish than that of conventional machining. Although there have been many studies on the micro-EDM, micro-WEDM, and laser micromachining of aluminum alloys, composites,

and ceramics, there was very little focus on improving those challenges. The heat-affected zone can affect the mechanical properties of the final product, and the poor surface finish can negatively impact the product performance. Therefore, those two issues need to be addressed in the future research on nonconventional micromachining of aluminum alloys.

- One of the major advantages of micro-EDM over conventional micromachining processes is that micro-EDM allows the fabrication of parts with thin walls and intricate features because of negligible cutting forces during machining. However, very few studies have focused on fabrication of intricate and complex-shaped parts using micro-EDM. Therefore, future research should focus on the application of micro-EDM in the fabrication of complex micro-features that are difficult to machine in aluminum alloys using conventional micromachining processes.
- There have been minimal research studies on the changes in microstructure and mechanical properties in the aluminum alloys after micromachining processes. As most of the micromachining processes apply either mechanical or thermal energy to remove materials, the mechanical properties of the final part may get affected. Future research studies should consider investigating this aspect of the micromachining.
- Finally, many of the studies on the literature focused on making simple structures, rather than focusing on application-oriented microstructures and devices. Therefore, future research should focus on collaborating with industries and conducting application-oriented research projects, so that the micromachining can be adopted in the industries as the optimum process for machining aluminum and its alloys at micro scale.

Microstructural Changes During Annealing of Aluminum Alloy: Modeling

Soheila Shabaniverki and S. Serajzadeh

Department of Materials Science and Engineering, Sharif University of Technology, Tehran, Iran

Abstract

Determination of microstructural events during heat treatment operations is an important task to obtain the desired microstructures and mechanical properties. Accordingly, during heat treatment of materials that have high stacking fault energy such as aluminum alloys, concurrent occurrence of recovery and recrystallization needs to be considered. On the other hand, the annealing processes may be performed under non-isothermal conditions in which a part of softening process is carried out during heating and/or cooling stage, particularly for the case of large-scale products. Thus, for estimation of softening fraction and microstructural events, different types of problems need to be taken into account such as the deformation analysis, the kinetics of metallurgical events, and heat conduction problem. In this entry, a combined analysis is discussed to manage the above-mentioned phenomena employing the finite element analysis together with cellular automata (CA) modeling. For this purpose, the distribution of plastic strain and the stored energy after cold rolling are determined utilizing finite element formulation, while they are considered as the initial conditions for the microstructural modeling. In the next stage, a two-dimensional CA coupled with a first-order equation is used to assess the softening rate, while a thermal finite element analysis is simultaneously employed to define temperature distribution during non-isothermal annealing. The model is then examined on softening behavior of cold-rolled AA1050 plate.

Keywords: Aluminum alloy; Cellular automata; Cold rolling; Finite element analysis; Recovery; Recrystallization.

LIST OF SYMBOLS

α^e	Elemental temperature vector ($^{\circ}\text{C}$)	P_{se}	Driving pressure owing to stored energy (N/m^2)
A_n	Area of new nuclei (m^2)	Q	Maximum of crystallographic orientation difference in the CA analysis
b	Magnitude of the Burgers vector (m)	Q_0	Recovery activation energy (kJ/mole)
c_p	Specific heat ($\text{J/kg}^{\circ}\text{C}$)	Q_b	Activation energy of grain boundary migration (kJ/mole)
C	Capacitance matrix in the thermal analysis ($\text{J}/^{\circ}\text{C}$)	QN	Activation energy for nucleation in recrystallization model (kJ/mole)
D	Damping matrix due to wave property in mechanical analysis (Ns/m)	R	Universal gas constant (J/K mole)
G	Shear elastic modulus (N/m^2)	S	Surface of deforming body (m^2)
h_a	Convection heat transfer coefficient ($\text{W/m}^2\text{C}$)	S_i	Crystallographic number assigned for each CA grain
k	Thermal conductivity ($\text{W/m}^{\circ}\text{C}$)	t	Time (s)
K	Stiffness matrix in the thermal finite element analysis ($\text{W}/^{\circ}\text{C}$)	T	Workpiece temperature ($^{\circ}\text{C}$)
M^e	Mass matrix (kg)	T_a	Surrounding temperature ($^{\circ}\text{C}$)
M_i	Number of cells that belong to grain “i”	u_i	Displacement tensor (m)
M^e	Elemental mass matrix (kg)	u_e	Elemental nodal displacement vector (m)
n	Normal direction to the surface boundary	v	Grain boundary velocity (m/s)
N	Shape function matrix	V	Volume of deforming body (m^3)
P	Total driving pressure for grain boundary migration (N/m^2)	x	Width direction of the strip (m)
P_c	Driving pressure owing to boundary curvature (N/m^2)	X	Fraction of transformation
		y	Thickness direction of strip (m)
		α	Dislocation interaction term
		γ_1	Grain boundary energy of deformed alloy (J/m^2)

γ_2	Grain boundary energy of recrystallized alloy (J/m ²)
γ_m	High-angle grain boundary energy (J/m ²)
λ	Cell size in the CA model (m)
Δt	Time step used in the finite element modeling (s)
Δt_{CA}	Time step used in the CA model (s)
ε_{ij}	Strain tensor
ρ	Density in mechanical model (kg/m ³), dislocation density in microstructural model (1/m ²)
ρ_f	Dislocation density of fully annealed material (1/m ²)
σ_0	Yield stress of deformed alloy (N/m ²)
σ_f	Yield stress of fully annealed alloy (N/m ²)
σ	Instantaneous yield stress in recovery model and predicted stress in mechanical model (N/m ²)
σ_{ij}	Cauchy stress tensor (N/m ²)
θ	Misorientation of a grain boundary
θ_m	Misorientation of a high-angle grain boundary

INTRODUCTION

Non-isothermal heat treatments of cold-worked aluminum alloys are significant operation in industrial purposes during which both recovery and recrystallization might be operative at the same time leading to significant changes in microstructures and material properties.^[1] In this regard, various models and approaches have been employed for predicting the influences of restoration phenomena on final microstructures^[2] including Monte Carlo modeling,^[3–5] vertex simulation,^[6–8] molecular dynamic,^[9] and cellular automata (CA).^[10–12] For instance, Schafer et al.^[13] introduced a three-dimensional CA for modeling recrystallization in the case of non-isothermal heat treatments, and they also considered the interaction of recrystallization and recovery. Salehi and Serajzadeh^[14] proposed a coupled CA and finite element model to evaluate static recrystallization kinetics during isothermal annealing of cold-rolled AA5052. Poorganji et al.^[15] investigated the impact of plastic strain on the recrystallization behavior and texture evolution within an aluminum alloy. Marx et al.^[16] developed a three-dimensional CA algorithm to simulate static recrystallization of cold-worked metals taking into account the influences of different aspects including recovery, nucleation, and grain boundary motion. Davies and Hong^[17] simulated static recrystallization of cold-rolled AA1050 using cellular automaton having different texture classes. Raabe^[18] proposed a CA-crystal plasticity modeling for determination of the yielding behavior of partially recrystallized aluminum alloys. Moreover, it can be mentioned other different works based on the CA for modeling of microstructural–mechanical behavior of various grades of deformable aluminum alloys.^[19–21]

In the published literature, it can be found that combined thermal–mechanical–metallurgical approaches may be of use for an accurate evaluation of material responses during practical heat treatment processes, during which various types of problems arise. Accordingly, in this

entry, a multi-scale model is discussed for evaluating softening kinetics in cold-rolled aluminum alloys under non-isothermal annealing conditions, while the model is examined on softening behavior of AA1050 plates.

MECHANICAL AND THERMAL MODELING

In the first place, it is required to estimate distribution of plastic strain and resulting internal stored energy within the deformed material. Different material models including rigid-plastic and elastic-plastic formulations have been proposed for simulation of cold-rolling operations.^[22–24] For instance, the principle of minimum potential power under dynamic conditions can be utilized for the case of elastic-plastic materials as follows:^[25]

$$\int \sigma_{ij} \delta \varepsilon_{ij} dV + \int \rho \ddot{u}_i \delta u_i dV + \int f_i \delta u_i dV - \int q_i^0 \delta u_i dS = 0 \quad (1)$$

where σ_{ij} is the stress tensor, ε_{ij} is the strain tensor, ρ is the density, u_i is the displacement tensor, f_i is the damping force tensor, and q_i^0 denotes the stress tensor acting on the roll/metal interface. $\ddot{u}_i$ is the second derivative of displacement tensor. The finite element form of the dynamic analysis can be derived as follows:^[26]

$$M\ddot{U} + D\dot{U} + KU = f \quad (2)$$

where U is the global nodal displacement vector, and D denotes the damping matrix due to wave property of deformation. M is the global mass matrix that remains constant during deformation, while the elemental mass matrix can be computed as follows:

$$M^e = \int N^T \rho N dV \quad (3)$$

where N denotes the shape function matrix for a vector variable. The displacement vector over each element is defined as $u = Nu^e$, in which u^e represents the nodal displacement vector for the element “ e ”. Note that iso-parametric elements may be used for discretization and construction of the meshing system, and the central difference scheme can be employed to solve the system of differential equation shown in Eq. 2.^[26] Finally, the distribution of strain and stress is possible to be computed by the interpolation techniques and integration of constitutive equations.^[25] In the next stage, the stored energy is defined based on the predicted local flow stress of the rolled plate. Note that the solution of finite element models has widely been mentioned in the literature,^[27–30] where the work-rolls might be taken as rigid bodies to reduce computation cost. Also, the constant friction factor, i.e., Coulomb friction model, is usually assumed to be operative on the roll/metal interface during cold-rolling processes, while one-half of the strip and one of the work-rolls are considered in the

calculations because of the existing symmetry. In the next step, flow stress within each deformed element, e.g., at the centroid of elements or at the employed Gausspoints, is computed and used to determine the local dislocation density according to the following equation:^[14,31]

$$\rho = \left(\frac{\sigma}{\alpha G b} \right)^2 \quad (4)$$

where G is the shear modulus, b is the magnitude of the Burgers vector, α is the dislocation interaction term that varies in the range of 0.3–0.6 for fcc and bcc metals,^[31] and σ is the predicted flow stress by the mechanical modeling.

After cold deformation processing, the heating stage should be applied to initiate the softening operation. Thus, it needs to predict the heating rate and temperature variations in different positions of the workpiece. Thus, a heat conduction problem should be solved using analytical methods or numerical approaches including the finite element analysis. In the case of plate-shaped sample, the heat conduction along length direction can be ignored and the heat transfer problem can be reduced to a two-dimensional one, while the governing equation can be described in Lagrangian framework as follows:

$$\frac{\partial}{\partial x} \left(k \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(k \frac{\partial T}{\partial y} \right) = \rho c_p \frac{\partial T}{\partial t} \quad (5)$$

where T is the temperature, x demonstrates the width direction, y shows the thickness direction of strip, k is the coefficient of heat conduction, and c_p is the specific heat. The following convection boundary conditions can be taken on the edges of the working domain in which the effect of radiation is excluded because of low-temperature annealing for the aluminum alloys, e.g., normally less than 550°C:

$$q_n = -k \frac{\partial T}{\partial n} = h_a (T - T_a) \quad (6)$$

where n is the normal direction to the surface boundary, T_a is the surrounding temperature, and h_a is the convection heat transfer coefficient that may vary at different sides, e.g., the bottom side in contact with the furnace wall and the upper side in contact with the furnace atmosphere. The above problem can be managed using standard Galerkin-finite element approach.^[32] In this approach, the weak formulation is first performed using the Gauss–Green theorem as follows:

$$\int_{dA=0} N^T \left(k \frac{\partial T}{\partial n} \right) dc - \int \left[\frac{\partial N^T}{\partial x} k \frac{\partial T}{\partial x} + \frac{\partial N^T}{\partial y} k \frac{\partial T}{\partial y} + N^T \rho c_p \frac{\partial T}{\partial t} \right] \quad (7)$$

Where c and A are the boundary and the area of working domain, respectively. N is the matrix of shape function for a scalar variable that is defined for a four-node iso-parametric element as follows:^[32]

$$N^T = \begin{bmatrix} \frac{1}{4}(1-\xi)(1-\eta) & \frac{1}{4}(1+\xi)(1-\eta) & \frac{1}{4}(1+\xi)(1+\eta) & \frac{1}{4}(1-\xi)(1+\eta) \end{bmatrix} \quad (8)$$

Where ξ and η are the natural coordinates. Note that using interpolation methods, the temperature over each element may be estimated as $T^e = NA^e$. Considering this interpolation, the above equation for each element is converted into a system of first-order differential equations as follows:^[33]

$$Ka^e + C \frac{da^e}{dt} = f \quad (9)$$

where a^e is the nodal temperature vector, and K and C are the conduction and the capacitance matrices, respectively. The vector f is due to the natural boundary conditions, i.e., q_n in Eq. 7. Different methods might be considered for the solution of the above system of ordinary differential equations including the central difference approach that leads to^[33]

$$\left[C_{i+1} + \frac{\Delta t}{2} K_{i+1} \right] a_{i+1} = \left[C_i + \frac{\Delta t}{2} K_i \right] a_i + f \Delta t \quad (10)$$

where a_{i+1} is the nodal temperature vector at the time $(i+1)$ th time step, and a_i is the initial temperature vector defined based on the initial condition or the solution for the previous time step. The solution of the above algebraic system of equation gives the nodal distribution vector for each time step, and with the aid of the interpolation techniques as stated above, it is possible to calculate temperature history in any specific region during heating and cooling stages. In the case of material nonlinearity, the heat conduction problem can be linearized by introducing a proper initial guess and iterative solution of the heat conduction problem.^[33]

RECOVERY AND RECRYSTALLIZATION MODELING

During heating stage, static recovery (SRV) initiates and leads to reduction of the internal stored energy. This is particularly important for the case of aluminum alloys having high rate of recovery.^[34,35] The rate of static recovery might be estimated by the following rate equation:^[34,36]

$$\frac{d\sigma}{dt} = -C_1 \exp \left[-\frac{Q_0 - C_2 \sigma}{RT} \right] \quad (11)$$

Where σ is the instantaneous flow stress, C_1 and C_2 are material constants, Q_0 is the recovery activation energy, R is the universal gas constant, T is the current temperature, and t is the recovery time. Under isothermal conditions, the above equation can be easily solved by a simple integration that leads to a logarithmic relationship.^[34] The isothermal annealing conditions can be particularly employed to determine the material constants and the activation energy for recovery. For this purpose, low-temperature heat treatments are performed under isothermal conditions, i.e., annealing in the salt bath, for different durations, and then, the yield stresses of the heat-treated samples are defined, and they are fitted to the above equation by nonlinear least square fitting method^[37] to assess the recovery parameters in different temperatures. Afterward, the rate of static recovery under non-isothermal conditions is possible to be computed by means of numerical solution of Eq. 11 coupled with the heat conduction problem explained in the previous section.^[38] Accordingly, the flow stress during annealing treatment is estimated based on the fourth-order Runge–Kutta scheme:

$$\sigma_{i+1} = \sigma_i + \frac{1}{6} \Delta t (k_1 + 2k_2 + 2k_3 + k_4) \quad (12)$$

where σ_{i+1} is the flow stress of the coming time step, and the coefficients in the above equation are computed as follows:^[37,38]

$$k_1 = f(t_i, \sigma_i) = -C_1 \exp\left(-\frac{Q_0 - C_2 \sigma_i}{RT_i}\right) \quad (13)$$

$$k_2 = f\left(t_i + 0.5\Delta t, \sigma_i + 0.5\Delta t k_1\right) \quad (14)$$

$$k_3 = f\left(t_i + 0.5\Delta t, \sigma_i + 0.5\Delta t k_2\right) \quad (15)$$

$$k_4 = f\left(t_i + \Delta t, \sigma_i + \Delta t k_3\right) \quad (16)$$

Based on the above procedure, a program can be developed to simultaneously predict thermal responses and variations in the yield stress and/or stored energy of the alloy during recovery under non-isothermal conditions. Note that the mechanical modeling may be performed by a finite element solver like Abaqus/Explicit, and then, the predicted data, i.e., predicted flow stress of cold-rolled plate, are taken as the input results for the temperature-recovery model.

At a higher annealing temperature, i.e., temperature higher than about 220°C, e.g., temperature higher than $0.5T_m$, static recovery and recrystallization can be operative, and thus, both processes should be considered at the same time. In order for simulation of recrystallization kinetics and the produced microstructure, CA model is coupled with the above-mentioned analysis. To do so, two-dimensional CA associated with an appropriate working domain, e.g., 500×500 square lattice having the periodic

boundary conditions with the cell size of $0.5 \mu\text{m}$, is considered, while the corrected Moore-type neighborhood algorithm may be used for handling the grain boundary movement.^[39] It is worth mentioning that the initial microstructure should be first generated by introducing randomly nuclei with defined orientations and then normal grain growth is applied.^[40] In the next stage, the generated normal grain structure is elongated by applying the uniform deformation technique^[41,42] in which a mapping is made to generate elongated grain structure by a pure-stretch deformation gradient matrix. Therefore, the following transformation can be utilized for generation of cold-rolled structure as follows:^[42]

$$\begin{bmatrix} u'_x \\ u'_y \end{bmatrix} = \begin{bmatrix} l_x & 0 \\ 0 & l_y \end{bmatrix} \begin{bmatrix} u_x \\ u_y \end{bmatrix} \quad (17)$$

where u'_x and u'_y represent the deformed positions, and l_x and l_y are the deformation parameters that are computed regarding the mechanical analysis. After generation of the deformed structure, the nucleation rate should be determined as a function of temperature and local stored energy. This is carried out by means of the following Arrhenius-type equation:^[43,44]

$$\dot{n} = c_0 \left(\frac{\sigma^2}{\alpha G} A_n - \frac{\sigma_f^2}{\alpha G} A_n - l_1 \gamma_1 + l_2 \gamma_2 \right) \exp\left(-\frac{Q_N}{RT}\right) \quad (18)$$

where $\dot{n}$ denotes the nucleation rate per width unit. Q_N and c_0 are the activation energies for nucleation and material constant, respectively. σ is the local yield stress of cold-rolled plate, and σ_f denotes the yield stress of the annealed alloy. A_n is the area of new nuclei. l_1 is the length of initial grain boundary for the case of heterogeneous nucleation, while for in-grain nuclei, this parameter is equal to zero. l_2 represents the length of the new nuclei which is assumed as the pyramid of the stable nucleus for the case of two-dimensional CA, and γ_1 and γ_2 are taken as the energies of the initial and the new grain boundaries, respectively. Note that the boundary energy might be defined based on the Read–Shockley model as follows:^[45,46]

$$\gamma = \gamma_m \frac{\theta}{\theta_m} \left(1 - \ln \frac{\theta}{\theta_m} \right) \quad (19)$$

where θ is the grain boundary misorientation, θ_m is the misorientation of high-angle grain boundaries, and γ_m is the high-angle grain boundary energy, while “ θ ” in the CA analysis can be computed as follows:^[47]

$$\theta = 2\pi \frac{|S_j - S_i|}{Q} \quad (20)$$

where Q is the maximum of crystallographic orientation, and S_j and S_i are the crystallographic numbers for

the neighboring grains. According to the classical theory of phase transformations, the nucleation in triple points occurred in the single-phase systems with the highest possibility,^[48] and then, the nucleation may take place on the high-energy grain boundaries and finally with the least possibility in the deformed grains particularly for heavily deformed materials. Thus, both heterogeneous and homogeneous nucleation mechanisms might occur depending on the amount of the stored energy imposed during previous deformation processing.^[40]

After establishment of new nuclei that are made by a probabilistic scheme,^[14] the growth rate of the stable nuclei or the existing grain boundaries should be defined. This is usually made by means of the following equation:^[49]

$$v = PM_0 \exp\left(-\frac{Q_b}{RT}\right) \quad (21)$$

where v is the grain boundary velocity, P denotes the driving pressure, M_0 is the material constant, and Q_b is the activation energy of grain boundary migration. Driving pressures owing to the stored energy together with the grain boundary curvature have both contributions on grain boundary movement. Hence, the total driving pressure is defined as follows:^[49,50]

$$P = P_{se} + P_c = \alpha G b^2 \Delta \rho_d + \kappa \gamma \quad (22)$$

where P_{se} and P_c denote the driving pressures due to the stored energy and curvature, respectively. b is the Burgers vector, κ is the boundary curvature, and $\Delta \rho_d$ is the change in dislocation density. Moreover, grain boundary curvature may be computed by Kink-Template technique:^[51,52]

$$\kappa = \frac{A}{\lambda} \frac{15 - M_i}{M + 1} \quad (23)$$

In the present approach, A and M are taken as 1.28 and 24, respectively, and M_i denotes the number of cells that belong to grain i . It should be noted that a program in MATLAB 7.6 is generated to handle heat conduction problem, the progress of recovery, and the CA modeling, while the deformation modeling and resulting distribution of plastic strain are determined by employing Abaqus/Explicit for a von Mises material. Accordingly, the following steps are taken into account in the modeling:

1. Determination of stored energy distribution based on the mechanical modeling of cold-rolling process.
2. The thermal modeling for determination of heating rate and temperature distribution in each time step during the transient stage.
3. During non-isothermal stage, the yield stress and the stored energy are predicted using the numerical solution of recovery model together with the results of the thermal modeling while under isothermal condition,

i.e., when the temperature of all positions reaches the annealing temperature, the variations in yield stress and dislocation density are defined under isothermal conditions.

4. For a temperature higher than the critical value, e.g., 220°C for 1XXX aluminum alloys, CA starts to work, while the impact of recovery on internal energy is calculated and applied in the CA model. The rate of changes in dislocation density is defined as follows:

$$\dot{\rho} = \dot{\sigma} \frac{d\rho}{d\sigma} = -\frac{2C_1\sqrt{\rho}}{\alpha G b} \exp\left(-\frac{Q_0 - C_2(\alpha G b \sqrt{\rho})}{RT}\right) \quad (24)$$

5. Calculations of the grain boundary curvature, mobility, and pressure are carried out at the current temperature, while the CA time step is determined according to the maximum grain boundary velocity, i.e., $\Delta t_{CA} = \lambda/v_{\max}$ and compared with the predefined critical time step, i.e., $\Delta t_{\text{Criteria}}$. If $\Delta t_{CA} < \Delta t_{\text{Criteria}}$, then finite element time step will be Δt_{CA} .
6. Determination of the new state of cells and also the temperature and the internal stored energy are updated.

MODELING RESULTS

The AA1050 plate was examined using the above-mentioned algorithm. In the first step, cold-rolling experiments followed by heat treatments were conducted on the aluminum plates under plane strain conditions. The samples with the dimensions of 120×50×4 (in mm) were first annealed for 1 hour at 370°C to remove the history of previous deformation history. Tensile testing according to ASTM-E8 was carried out on the annealed plate to assess flow stress behavior of the alloy. Then, the results were used in the mechanical analysis by means of the Johnson–Cook plasticity model for describing flow stress behavior of the deforming material.^[53] The annealed plates are cold rolled under single-pass, double-pass, and triple-pass rolling schedules with the total reduction of 50% as listed in Table 1. To find the material parameters for recovery model, the cold-rolled samples are then isothermally heat treated at temperatures of 160°C, 180°C, and 200°C for different durations. The yield stresses of annealed samples after different durations were determined by tensile testing with the cross-head speed of 1 mm/min. Also, isothermal annealing at 340°C was performed to assess the CA parameters including activation energies for nucleation and growth as explained in Ref. [40]. Additionally, the temperature history during non-isothermal heating was recorded in a few samples using a K-type thermocouple embedded at the mid-thickness of the heating plate. This was conducted to experimentally measure the proper heat convection coefficient of the furnace atmosphere that was determined as 30 W/m²°C. Finally, non-isothermal annealing

treatments were performed in the electric furnace with different temperatures of 200°C and 360°C. Heat treatments were done for different durations followed by mechanical testing and microstructural evolution. Optical metallography was conducted to determine microstructural events during high-temperature annealing process. The samples were first mechanically grounded and polished, and then they were electrolytically etched utilizing Barker's reagent containing 5% HBF_4 and 95% water. The utilized voltage was in the range of 15–30 V, while etching time was about 90 s. Afterward, mean grain size was measured by means of intercept method in which the grain count was made on five different straight lines. In addition, the local softening fraction was estimated by the Vickers microhardness test on the polished samples using the load of 100 gf. For instance, the results of hardness testing under non-isothermal annealing with a furnace temperature of 360°C are given in Table 2. Then, the softening fraction was evaluated experimentally using these data together with the following equation:^[54]

$$X_s = \frac{H_0 - H}{H_0 - H_f} \quad (25)$$

where H_0 , H , and H_f are the hardness of as-deformed, partially annealed, and fully annealed samples, respectively. It should be mentioned that a series of samples were examined for hardness measurements in which at least five indentations were made for each sample, and the mean value was reported as the related local hardness. The other set of samples were used in microstructural evolution for the alloy heat treated in different durations.

Table 1 Rolling layouts used in the cold-rolling experiments

Sample	Reduction in the first pass (%)	Reduction in the second pass (%)	Reduction in the third pass (%)
Single-pass	50	—	—
Double-pass	25	25	—
Triple-pass	17	17	16

Table 2 The results of hardness testing for non-isothermally annealed sample

Sample	Annealing duration (s)	Hardness
Single-pass rolled	60	41
Single-pass rolled	200	37.9
Single-pass rolled	420	23.7
Triple-pass rolled	60	39.3
Triple-pass rolled	180	27.3
Triple-pass rolled	300	22.6

Figure 1 displays the predicted equivalent plastic strain under plane strain condition at the exit position of deformation zone for the case of double-pass rolling operation. As is expected, the plastic strain is distributed nonuniformly along thickness direction where the higher plastic strain is imposed at the surface region owing to the effect of deformation geometry and friction effect on the roll/metal interface.^[55] As noted earlier, the results of low-temperature annealing together with the least square fitting were used for determination of the recovery constants.^[38] Based on the achieved results listed in Table 3, the recovery behavior at low temperatures could be estimated; for instance, Fig. 2 compares the predicted and experimentally measured yield stresses of the cold-rolled AA1050 during non-isothermal annealing at 200°C in which the thermophysical properties have been taken as follows:^[1]

$$c_p = 738.8 + 0.537T \quad (26)$$

$$k = 248.08 - 0.05353T \quad (27)$$

As seen, there is a reasonable consistency between the two sets of data, and both of them show logarithmic decay of yield stress. Given the heating diagram, a part of the annealing occurred under transient conditions, while the rest took place under constant temperature. As a result, the heating rate, e.g., the furnace power, could significantly affect the rate of softening.^[38]

Fig. 2 The temperature history and the rate of non-isothermal recovery of AA1050

Table 3 Parameters used in the microstructural model

Parameter	Value
Q_0 (kJ/mole)	68
Q_N (kJ/mole)	140
Q_b (kJ/mole)	120
M_0 (M^4/JS)	0.1–0.3
C_2 (m^3)	1.62×10^{-28}
h ($W/m^2°C$)	30
G (GPa)	70
α	0.5
ρ (kg/m^3)	2700
Friction coefficient	0.1
σ_f (MPa)	85
γ_m (J/m^2)	0.324
θ_m	15°
b (m)	2.86×10^{-10}
λ (m)	0.5×10^{-6}

At higher annealing temperatures, both recrystallization and recovery are operative, while the occurrence of static recovery may change the rate of recrystallization.^[13] Thus, the prediction of the rate of static recovery and its interaction with recrystallization process are of significance. Figure 3 demonstrates optical images of recrystallized samples in surface regions of different rolled samples after non-isothermal annealing in a furnace having temperature of 360°C. As this figure shows, the recrystallized grain size of triple-pass rolled is smaller than the other

Fig. 3 Optical images of annealed sample at 360°C after 50% reduction, (a) single-pass rolled after 24 min, (b) double-pass rolled after 20 min, and (c) triple-pass rolled after 18 min

samples due to accumulation of shear strains in the successive passes. It should also be noted that the heating rate affects the recrystallization kinetics and microstructure evolution, while the surface region usually undergoes higher heating rate depending on the dimensions of the part being heat treated as well as its thermophysical properties. However, for the present case, the heating rates at the center and surface regions of the plates are almost comparable because of the thickness of the rolled plates, i.e., thickness of 2 mm, and the high thermal diffusivity of the examined aluminum alloy. Figure 4 shows temperature distribution under various convection coefficients, and therefore, different heating rates are imposed on the plates. The low heating rate of 30 $W/m^2°C$ increases in the first stage, and so, a large part of the softening processes are performed under the transient stage. On the other hand, for the higher heating rate, e.g., for the case of 100 $W/m^2°C$, the softening starts faster and a large part of recrystallization is carried out under a constant temperature.

Figure 5 compares the optical micrograph taken from the surface region and simulated microstructure of recrystallized sample for non-isothermal heat treatment

Fig. 4 The predicted heating rate for different heat convection coefficients at the depth of 0.2 mm from surface

Fig. 5 Optical images and predicted microstructure for samples with 50% reduction and annealed at 360°C at surface regions, (a1) real image for single-pass rolled plate, (a2) real image for double-pass rolled plate, (a3) real image for triple-pass rolled plate, (b1) simulated result for single-pass rolled plate, (b2) simulated result for double-pass rolled plate, and (b3) simulated result for triple-pass rolled plate

with a furnace temperature of 360°C and a heat convection coefficient of 30 W/m²°C. Note that the simulation was made using the parameters listed in Table 3 that is derived for AA1050.^[40] The average grain sizes for surface regions of the predicted and real microstructures were determined about 40 and 32 μm in the single-pass rolled sample, 26 and 23 μm in the double-pass rolled sample, and about 19 and 17 μm for the triple-pass rolled layout, respectively. As seen, mean grain size and grain morphologies of the predicted microstructures and the real ones are in reasonable agreement. Furthermore, the rolling pass dependence of the recrystallized grain size is clear in this figure. Figure 6 shows the real and the simulated microstructures for the central region of the single-pass rolled sample under the same annealed conditions. As mentioned in previous sections, the recrystallized microstructures of single- and multi-pass rolled samples at central regions are almost comparable because of the similar plastic strain^[40] and the equivalent heating rate. It also should be noted that the central region recrystallized grains are relatively larger than the surface zone. This is because the stored energy for recrystallization process in surface zone is higher than

the central region owing to inhomogeneity in strain field as shown in Fig. 1. Figures 7 and 8 demonstrate the nucleation and growth steps in recrystallization process in various times for the surface region for single- and triple-pass rolled samples under non-isothermal condition in a furnace having temperature of 360°C and heat convection coefficient of 30 W/m²°C. The nucleation process for the triple-pass rolled plate occurs in triple points, grain boundaries and within the grains in a few positions because of the high stored energy of this region; however, for the other sample, it mainly occurs in triple points and grain boundaries. It is attributed to less stored energy in the deformed grains leading to low probability of homogenous nucleation. Note that under non-isothermal annealing, the reduction in dislocation density is calculated by means of recovery model. At low temperatures, recovery is the main mechanism of softening process and significantly controls the softening rate, while at higher temperatures, both static recovery and recrystallization participate in softening process and compete with each other. For instance, Fig. 9 shows the different stages of softening kinetics predicted for single-pass rolled plate at 380°C and 240°C under the convection heat

Fig. 6 Microstructure at the central region for the single-rolled sample with 50% reduction and annealed at 360°C: (a) real image and (b) simulated result

Fig. 7 The progress of recrystallization in the single-pass rolled plate annealed in a furnace having temperature of 360°C

Fig. 8 The progress of recrystallization for triple-pass rolled plate annealed in a furnace having temperature of 360°C

Fig. 9 The different stages of softening kinetics at 380°C and 240°C for single-pass rolled plate

transfer of 100W/m²C. As seen in this figure, at the temperature of 240°C, the dominant softening process is the static recovery. On the other hand, at the temperature of 380°C, softening mechanism includes both recovery and recrystallization.

The predicted and the experimentally measured softening kinetics in single- and triple-pass rolled plates at the surface region under non-isothermal annealing conditions are compared in Fig. 10. This figure shows a reasonable consistency between the real data and the

simulation results. As mentioned, the imposed plastic strain in triple-pass rolling is greater than those in the other samples. This results in higher dislocation density and internal stored energy, which, in turn, leads to higher rate of softening kinetics. Usually, the recrystallization rate provides an S-shaped diagram. However, the softening rate that includes both recovery and recrystallization shows a more sophisticated behavior compared to a regular S-shaped diagrams. According to this figure, the early stage of annealing is dominated by recovery process,

Fig. 10 Measured and predicted softening fraction at surface regions of single- and multi-pass rolled samples non-isothermally annealed in the furnace having temperature of 360°C and heat convection coefficient of 30 W/m²°C

and the recrystallization has trivial impact on softening process, but as the heating proceeds, both recovery and recrystallization are responsible for softening process. In

this stage, the nucleation and growth of new grains through deformed structure play gradually a more important role, and recovery kinetics becomes slower. The softening fraction was calculated based on the variation in dislocation density as follows:^[14]

$$X_{ps} = \frac{(\rho_0)^{0.5} - (\rho_t)^{0.5}}{(\rho_0)^{0.5} - (\rho_f)^{0.5}} \quad (28)$$

where X_{ps} is the predicted softening fraction, ρ_0 is the dislocation density of the deformed material, ρ_t is the dislocation density of annealed sample after time “ t ,” and ρ_f is the dislocation density of fully annealed material. Finally, Fig. 11 displays the predicted recrystallized fraction during non-isothermal annealing for the single-pass rolled plate under various heating rates in a furnace having temperature of 360°C. As expected, the incubation time decreases, while the rate of recrystallization becomes faster under higher rate of heating. This figure particularly shows the potential of the above algorithm as a tool for designing an appropriate schedule under practical working conditions. It should be noted that the mentioned algorithm can also be used for other aluminum alloys; however, the proper materials parameters have to be defined by means of the experimental testing as explained in this section.

Fig. 11 Progress of static recrystallization at the surface region of single-pass rolled plate under various heating rates

OUTLOOK

The softening behavior and microstructural evolution in cold-worked aluminum alloy during non-isothermal annealing can be estimated by a combined mechanical–thermal–microstructural analysis. This approach makes it possible to estimate the grain structure, the stored energy and its distribution throughout the workpiece, the heating rate during annealing treatment as well as the rate of static recovery and recrystallization at the same time. Non-isothermal annealing of cold-rolled AA1050 is then examined by the model. The comparison between the experimental and the predicted results indicates a reasonable consistency that validates the employed methodology and verifies the achieved results. The results of the model indicate that multi-scale simulation could be efficiently utilized for designing a proper layout to assess the required microstructure as well as the desired mechanical properties after cold-working and annealing processes.

Abstract

High-pressure die casting (HPDC) components are known to be not heat treatable due to the formation of unacceptable surface blisters, dimensional instability, and poor mechanical properties during conventional solution treatment, such as at 540°C for 8 h. In the present study, the possibility of solution treating a recycled ALDC12 HPDC alloy at temperatures less than 500°C and with shorter solution treatment times was investigated. HPDCs with thickness of 2 and 3 mm were solution treated at 490°C for various times ranging from 15 to 180 min. Microstructural evolution during solution treatment was examined by various techniques, including metallography, energy dispersive spectrometry, electrical conductivity, and X-ray diffraction. Results indicated that almost all of the Al_2Cu intermetallics were dissolved within 90 min of solution treatment. The coarsening of eutectic Si particles was found to follow the Lifshitz–Slyozov–Wagner theory with two distinct regimes. Furthermore, measurements of Cu concentration within α -Al dendrites revealed that the diffusion of Cu atoms in α -Al phase is not the primary limiting factor for homogenization of the alloy. Most importantly, no blisters were observed at the surface of the castings. Therefore, this heat treatment can be used for HPDC components from ALDC12 alloy at a reasonable time.

Keywords: ALDC12 alloy; Diffusion; Heat treatment; Homogenization; Intermetallics.

INTRODUCTION

ALDC12 (A383) is one of the most widely used aluminum alloys in high-pressure die casting (HPDC) of thin-wall and high-integrity components for the automotive industry. This wide use can be attributed to its high specific strength, high fluidity, high corrosion resistance, and low shrinkage during solidification.^[1–10] Typically, a heat treatment schedule that yields a T6 temper is recommended for full enhancement of the mechanical properties for ALDC12, to take advantage of the precipitation strengthening potential of the alloy.^[11,12] To attain T6 temper, parts are first solution treated, quenched, and subsequently aged artificially to peak strength condition.^[13–15] In Al–Si–Cu–Mg alloys, the solution treatment results

in^[11,12,15–18] the homogenization of the solutes, dissolution of Al_2Cu and Mg_2Si to maximize the amount of hardening solutes in the aluminum matrix, and modification of the morphology of eutectic silicon. Therefore, the initial as-cast microstructure affects the alloy's response to heat treatment.

The as-cast microstructure of ALDC12 alloy consists mainly of a solid solution α -aluminum, eutectic Si, Fe-rich intermetallics, and Cu-bearing intermetallics. Depending on the solidification conditions, Cu-bearing intermetallics can have different morphologies: eutectic ($\text{Al–Al}_2\text{Cu}$), blocky Al_2Cu , or a mixture of both types.^[13,19,20] High solidification rates and modification with Sr promote the formation of eutectic ($\text{Al–Al}_2\text{Cu}$) and blocky Al_2Cu , respectively.^[21–26] It has been reported^[27] that blocky

Al_2Cu probably acts as nucleation site for the fine eutectic Al_2Cu that forms during the later stages of solidification. The formation mechanisms of Cu- and Fe-bearing intermetallics are beyond the scopes of this study and are discussed elsewhere in more detail.^[13,19,20,22,27,28]

Solution treatment needs to be long enough to dissolve Mg_2Si (β) and Al_2Cu particles completely, so that solutes are available for precipitation at strengthening sizes during subsequent aging. Concurrently, solution treatment time, t_{ST} , should be as short as possible to save energy costs. Moreover, secondary porosity with deleterious effects on the mechanical properties^[24] can form at long t_{ST} . HPDC components usually contain internal pores in which gases such as air, hydrogen, or vapors formed by the decomposition of organic die wall lubricants are entrapped. The size distribution and number density of these pores are strongly affected by the HPDC process parameters.^[29] The gases entrapped inside the pores expand during conventional solution treatment (above 500°C for more than 8 h) causing unacceptable surface blistering and dimensional instability of the castings. Therefore, conventionally produced HPDC components are usually considered to be not heat treatable.^[30,31]

The effects of solution temperature,^[27] Sr addition,^[32] Mg content,^[28] Fe content,^[32] and fraction of Al_2Cu particles^[27,32] on homogenization have been investigated. However, the effect of microstructure has not been addressed so far, to the authors' knowledge. The present study has been conducted to study the effect of microstructure on solution treatment of high-integrity die castings of ALDC12 alloy castings with wall thicknesses of 2 and 3 mm.

EXPERIMENTAL PROCEDURE

The chemical composition of the recycled ALDC12 alloy used in the study, as determined by optical emission spectrometry, is provided in Table 1. The alloy was received as 5 kg ingots, which were then melted at 750°C in an electric furnace. The melt was held at 680°C in a holder. Specimens, shown in Fig. 1, were prepared by using TOSHIBA cold chamber die casting machine. Each casting in Fig. 1 had two sections with wall thicknesses of 2 and 3 mm. The casting and HPDC machine parameters are listed in Table 2.

Castings were solution treated at 490°C^[18] for 15, 30, 60, 90, 120, and 180 min in an air circulating furnace and were subsequently quenched in water at 25°C. Tensile test specimens were machined according to ASTM B557. Four tensile test specimens were prepared for each solution treatment time and section thickness. For simplification, specimens

from the section with thickness of 2 mm and the section with thickness of 3 mm are called W2 and W3, respectively.

Microstructural changes were examined on polished surfaces of metallographic specimens obtained from the as-cast and solution-treated test bars. The specimens were chemically etched using Keller's reagent. A Nikon Eclipse MA 200 optical microscope, a FEI Quanta 200F FE-SEM equipped with EDS, and Image-Pro Plus software were used to characterize the microstructure of the samples. An X-ray diffractometer (BRUKER D8 Discover, Monochromatic Cu-K α source, $\lambda = 0.15406$ nm, scanning interval of 0.02°) was used to determine the lattice distortion of α -Al during solution treatment.

RESULTS AND DISCUSSION

As-Cast Microstructure

Figure 2 shows optical micrographs of the alloy in the as-cast condition. Image analysis of the as-cast microstructure revealed that the average size of α -Al dendrites was 8.4 and 12.4 μm for the W2 and W3 samples, respectively.

Figure 3 shows the SEM images obtained from W2 and W3 samples in the as-cast condition, showing that both W2 and W3 samples contained eutectic Si phase with a lamellar morphology. Figure 3a,b shows the microstructure of both samples contains iron and copper-bearing intermetallics. Based on their morphologies, Fe-bearing phases are interpreted as β - Al_5FeSi platelets^[33] and Cu-bearing phase as Al_2Cu .

Microstructure after Solution Treatment

Figures 4 and 5 show the evolution of eutectic Si particles during solution treatment of W2 and W3 samples, respectively. Lamellar eutectic Si particles that were observed in the as-cast microstructure of the alloy (Fig. 3), transformed to fine and fibrous particles in solution-treated samples. Transformation of lamellar Si particles into a large number of finely dispersed particles can be attributed to the necking and fragmentation during the early stages of solution treatment.^[34–36] From the series of micrographs in Figs. 4 and 5, it can be stated that the Si particles became larger and more spherical with increasing solution treatment time, which is consistent with the previous results.^[15,26,34–38] The driving force for coarsening and spheroidization of Si particles is the reduction of interfacial energy due to reduction of surface area per unit volume.^[39] It is also important to mention that no blister was observed in the solution-treated samples.

Table 1 Chemical composition of the examined alloys

Element	Si	Fe	Cu	Mn	Mg	Ni	Zn	Ti	Al
wt%	11.83	0.827	2.365	0.169	0.255	0.054	0.516	0.028	Bal

Results of image analysis from SEM images are presented in Fig. 6, in which each point represents the average of approximately 1000 individual measurements. In both as-cast and solution-treated conditions, the average area of eutectic Si particles in W2 samples was smaller than that in W3 samples. This difference is mainly because of faster solidification in W2 samples than in W3. Moreover, for both W2 and W3 samples, the size and aspect ratio of Si particles decreased significantly within the first 15 min of solution treatment, indicating that the eutectic silicon became fragmented and rounder during solution treatment,

Fig. 3 SEM images showing the as-cast microstructure obtained from (a and b) W2 and (c and d) W3 samples

Fig. 6 Effect of t_{ST} on (a) mean area and (b) aspect ratio of eutectic Si particles. Each point represents the average of approximately 1000 individual measurements

as evidenced in Figs. 4a and 5a. Although, increasing t_{ST} from 15 to 30 min increased the mean area of Si particles considerably, the aspect ratio of Si particles increased slightly with increasing the t_{ST} past 30 min.

Electrical Conductivity

Electrical conductivity measurements (according to International Annealed Copper Standard – IACS) were taken to study the effect of solution treatment on the evolution of eutectic Si particles. The method of testing and assessment of the results are explained in the authors' previous work.^[40] The conductivity of the annealed copper (5.8001×10^7 S/m) is defined to be 100% IACS at 20°C. All other conductivity values are related back to this conductivity of annealed copper. Therefore, %IACS = (172.41/resistivity)

Fig. 7 (a) Effect of solution treatment on the electrical conductivity (%IACS) of ALDC12 alloy used in this study. Schematic representation of electron collisions with the eutectic silicon phase: (b) coarse and (c) finer^[41]

where resistivity ρ is in micro ohms per centimeter. From the results presented in Fig. 7a, solution treatment for 15 min increased the %IACS from 25.53% to 30.22% and from 24.47% to 30.30% for W2 and W3 samples, respectively. This significant increase in %IACS can be attributed to the fragmentation of long lamellar eutectic Si particles into finely-dispersed smaller particles during solution treatment, which was also indicated in Fig. 6a. The continuous silicon plates of unmodified alloys effectively block the flow of electrons (Fig. 7b). The reduced projected area of finer silicon particles increases the available cross-sectional area of the conducting α -Al phase (Fig. 7c)^[41] and results in the increased conductivity observed in Fig. 7a. However, it can be seen that the values of %IACS did not change with further increase of t_{ST} . This result reinforces the finding that the major changes in morphology eutectic Si particles took place during the first 15 min of solution treatment.

Although increasing t_{ST} from 15 to 30 min significantly increased the size of Si particles, it did not change %IACS of the alloy. Therefore, it can be concluded that the size of Si particles is not the primary factor that influences the electrical conductivity of examined alloy. The trend of changes in aspect ratio of the Si particles seems to be correlated more with the variations of %IACS. Hence, aspect

ratio of the Si particles may have a significant effect on the electrical conductivity of the alloy.

It is reported^[15] that coarsening and spheroidization of Si particles are diffusion-controlled processes and are directly proportional to the temperature and time of solution treatment. Therefore, these processes can be described by the Lifshitz–Slyozov–Wagner (LSW) theory of Ostwald coarsening,^[42,43] which states

$$d^3 - d_0^3 = kt_{ST}, \quad (1)$$

where d is the Si particle diameter, d_0 is the initial diameter, and k is a constant. The change in d^3 with t_{ST} is presented in Fig. 8, with the dotted lines representing the linear fits. It is clear that there are two regions of coarsening with distinct differences in the value of k . This result is noteworthy,

Fig. 8 Evolution of the average eutectic Si diameter (d) as a function of isothermal soaking time at 490°C. Dotted lines represent evolution according to $d^3 - d_0^3 = kt$. The unit for the coarsening constant k is $\mu\text{m}^3 \text{min}^{-1}$. R^2 is the coefficient of determination

and it can be hypothesized that Si particles grow as well as coarsen in the early stages of solution treatment, resulting in a distinctly different slope. This hypothesis requires further investigation.

Energy Dispersive Spectroscopy Results

To evaluate the severity of coring in the as-cast samples and the degree of homogenization during solution treatment, Cu concentration measurements were taken across dendrite arms via energy dispersive spectroscopy (EDS). The results are presented in Fig. 9. Five points were measured over a dendrite arms. To reduce operator bias, only dendrites that intersected a specific Y-stage coordinate were analyzed, regardless of their size. At least 20 dendrites were analyzed for each data point in Fig. 9. Results indicate that the concentration of Cu at the edge of primary α -Al dendrites (adjacent to the eutectic regions) was more than 1.5 wt% for both W2 and W3 samples in the as-cast condition. The concentration of Cu in the center of dendrites for both W2 and W3 samples was less than 0.2 wt%. This considerable segregation, i.e., coring, of copper in both samples occurred due to the nonequilibrium solidification during HPDC.^[44] The measured concentrations of Cu in the center of the dendrites of the as-cast Al–Si–Cu alloys show some scatter. For example, in Ref. [28], Cu concentration of 1.2 wt% was reported for an Al–7Si–3.5Cu alloy with a dendrite arm spacing (DAS) of 40 μm , while the Cu concentration was reported^[45] to be 0.64 wt% in the same alloy with DAS = 10–19 μm . Additionally, the Cu concentration was found^[21] to be 0.74–0.82 wt% in an Al–7.8Si–3.1Cu alloy with a DAS of 10–50 μm . The variations in the Cu concentration arise from several reasons including^[21]

- For fine microstructures with SDAS around 10 μm (as for the present study), the spot size is large compared to the SDAS. Therefore, a larger part of the

Fig. 9 EDS results showing the effect of t_{ST} on the concentration of Cu across α -Al dendrites in HPDC samples with a wall thickness of (a) 2 mm and (b) 3 mm

dendrite would be included in the measurement of Cu concentration than for the coarser microstructures. This gives higher concentration of Cu in fine microstructures.

- The variation could also be due to differences in the measurement technique that is employed.
- The measured concentration in the dendrite center depends on the ability to measure a dendrite that is cut through the center.
- Coarseness of the microstructure can affect the measurement. The longer time that is available for back diffusion gives a higher Cu concentration in coarser microstructures.

To model homogenization of an Al–Si–Cu alloy, Sjölander and Seifeddine^[26] assumed that the diffusion of Cu in Si eutectic is fast, and the diffusion of Cu in the α -Al phase will control the rate during the solution treatment of Al–Si–Cu alloys. Similarly, Samuel et al.^[27] reported that in a 319.2 alloy with SDAS of 22 μm , dissolution of Al_2Cu phase takes several hours, due to the low diffusion rate of Cu in Al. However, results in Fig. 9 indicate that the concentration of Cu at the edge and in the center of dendrites are approximately the same for all solution-treated samples. Hence the diffusion rate of Cu in α -Al is not rate-controlling for homogenization, at least within the experimental region of this study. This result is in contrast to those reported by Sjölander and Seifeddine^[26] and Samuel et al.^[27] This can be attributed to the effect of microstructure, specifically DAS. The rate of homogenization depends on both the diffusion coefficient of Cu and the coarseness of microstructure. During the solution treatment of castings with coarse microstructure with large DAS, the diffusion distances are longer and therefore the diffusion of Cu atoms can be regarded as rate-controlling. In finer microstructures, homogenization is achieved after a short solution treatment time and the diffusion of Cu does not control the rate of homogenization.

Another factor that can affect the homogenization of Al–Si–Cu castings is the morphology of Al_2Cu particles. Although both blocky and eutectic Al_2Cu have the same stoichiometry, their response to solution treatment is vastly different. The eutectic Al– Al_2Cu dissolves by fragmentation into smaller particles. Subsequently, these particles spheroidize and finally dissolve by radial diffusion of Cu into the surrounding matrix. The blocky Al_2Cu does not fragment due to its lower interfacial energy with the surrounding matrix. It dissolves by spheroidization and radial diffusion of Cu atoms into the surrounding matrix, which requires longer time.^[26,28]

Results in Fig. 9 show that increasing t_{ST} from 15 to 90 min constantly increased the concentration of Cu in center and at the edge of dendrites for both W2 and W3. Therefore the dissolution of Al_2Cu particles in the eutectic region continued until 90 min, beyond which

the concentration of Cu within the dendrites remained essentially constant.^[46,47]

Lattice Parameter

The lattice parameter of the α -Al in the as-cast and solution-treated samples were determined using diffraction peaks of the (111) plane obtained by X-ray diffraction and the application of Cohen's method.^[48] The results are presented in Fig. 10. The lattice constant for the as-cast W2 and W3 samples were 0.4049 and 0.4050 nm, respectively. The lattice constant of both W2 and W3 samples after 90 min of solution treatment were 0.4040 and 0.4045 nm, respectively. For both W2 and W3, the lattice parameter was found to constantly decrease with increasing t_{ST} to 90 min. It is very well known that the addition of Cu to the solid solution (α -Al) decreases the lattice constant of α -Al because the atomic radius of Cu (0.126 nm) is smaller than that of Al (0.142 nm).^[49–51] Therefore, solution treatment until 90 min increased the Cu concentration in α -Al phase. Solution treatment beyond 90 min, however, did not result in further reduction of lattice constants. Hence, the concentration of Cu in α -Al phase did not increase with solution treatment time after 90 min. These findings are in agreement with the results obtained from EDS analysis.

The difference in lattice parameters of as-cast W2 and W3 can be attributed to the different solidification rates that influence the extent of coring within the dendrites. The higher the solidification rate, the stronger the coring and the less the concentration of the Cu within dendrites. Therefore, the smaller lattice constant of α -Al in W2 compared to that of W3 is due to the lower concentration of Cu within dendrites of W2 compared to that of W3.

Fig. 10 Effect of solution treatment on lattice constant of α -Al phase

CONCLUSIONS

The present study aimed to investigate the microstructural evolutions of ALDC12 alloy during solution treatment. The following conclusions can be drawn from the results:

- The lamellar eutectic Si particles in the as-cast microstructure are fragmented into smaller, rounder particles in the early stages of solution treatment at 490°C. With increasing solution treatment time beyond 15 min, the size of Si particles increased while the aspect ratio did not change considerably.
- Using LSW theory, it was found that the coarsening of Si has two different mechanisms depending on the time of solution treatment (i.e., size of Si particles). The growth coefficient (k) for each mechanism was also determined. Comparison of the values of growth coefficients shows that rate of coarsening of Si particles decrease with increase in the size of Si particles.
- Examination of Cu concentration within the α -Al dendrites revealed significant coring in the as-cast samples. However, coring was eliminated very quickly, and no coring was observed after a solution treatment for 15 min. Increasing of solution treatment time to 90 min increased the Cu concentration within the dendrites, beyond which Cu concentration remained constant. Therefore, Cu-bearing intermetallics were completely dissolved after 90 min of solution treatment. This finding was confirmed by the results obtained from the measurement of lattice constant of α -Al phase.
- It is significant that no blister was observed on the surface of the samples. Therefore, solution treated for 90 min at 490°C can be successfully applied on HPDC components of ALDC12 alloy.

Abstract

In this work, the structural changes induced by the chemical nature of alloyed elements and aged treatment showed a beneficial connection with hardness and electrochemical degradation performance. Al-based alloys were investigated by means of the Vickers hardness test, in order to determine the effect of aging treatment on the hardness; X-ray diffraction and scanning electron microscopy were used to identify the phase transformation by the casting and ageing treatment; finally, a short-term electrochemical test to know the electrochemical performance. The results show that the formation of the $(\text{MgZn})_{49}\text{Al}_{32}$ phase occurs under two conditions: when the magnesium content is more than 5.49% in as-cast condition, and the thermal treatment carried out at 450°C for 5 h. In addition, the hardness and electrochemical performance have been influenced by the presence and quantity of the $(\text{MgZn})_{49}\text{Al}_{32}$ phase. The addition of magnesium alloy modifies the microstructure, increases the content of the $(\text{MgZn})_{49}\text{Al}_{32}$ phase, and provides a localized corrosion, which leads to the breakdown of the oxide film ($\gamma\text{-Al}_2\text{O}_3$) formed on the Al alloy surface.

Keywords: AlZnMnMg alloy; Corrosion; Electrochemical performance; Hardness; Short electrochemical test; Structure.

INTRODUCTION

Combined with total life cycle cost, the alloys produced from Al, Zn, and Mg as metallic alloying elements are considered effective substitutes for a number of ferrous and nonferrous alloys.^[1] It is well known that the alloys based on aluminum are considered lightweight and cost-effective materials. Additionally, a wide range of applications involves the grouping of high strength and corrosion resistance materials. Based on these considerations, we have studied the Al-Zn-based alloys, which combine their ductility and conformability with low-density, excellent castability, high specific strength, and high hardness.^[2] Even more, the investigated material retains the characteristic of the Al-Zn alloys and almost all aluminum alloys, that is, recyclability after serving the original purpose. When compared with conventional Al-alloys, the Al-Zn alloy exhibits an explicit property as a protector material

based on the current capacity delivered, which increased significant interest in studying this alloy as a galvanic material.^[3] The galvanic material, also named anode, is applied to any metallic structure in contact with a bulk electrolyte. Keeping this in mind, the current capacity of the Al-Zn alloy could be enhanced by carefully selecting the chemical nature of solutes; their concentration and appropriate thermal treatment are explored in this work. Continuing on these lines, the alloy studied in this article is aluminum based, because aluminum exhibits an anodic dissolution process, low active electrode potential (−950 to −1200 mV), and high theoretical current capacity.^[4] Aluminum is alloyed with zinc and magnesium; these elements support the physical and chemical parameters and increase the performance as galvanic material. It is noteworthy that this chemical combination makes this alloy to behave as an excellent galvanic material, with significant effect on preventing passivation of aluminum, which

avoids developing a non-conducting film on their surfaces. To prevent passivation, extensive efforts hint at the possibility of activating the aluminum alloys with elements such as indium tin, mercury, and bismuth. These chemical elements alloyed with aluminum stimulate the formation of segregated phase that limits the passivation and increases the galvanic behavior.^[5,6] Fortunately, available data suggest that the precipitation of intermetallic phases formed from some non-contaminant elements after the heat treatment has excellent potential to prevent passivation. Considering this, the present contribution aims at a chemical element alloyed with Al-Zn that averts passivation and at a special thermal treatment that in most cases improved the strong age hardening given to the system their unique combination of lightweight and high mechanical properties.^[7,8] Considering this, this article emphasizes the precipitation behavior because the Al-based alloys exhibit several transformation sequences during ageing.^[9] Hence, the fine precipitation of $(\text{MgZn})_{49}\text{Al}_{32}$ and MgZn_2 phases during heat treatment is very much focused in this work. The formation of solute-rich precipitates begins from the super-saturated solid solution (SSS) α -aluminum matrix. These phase precipitates develop the strategy for further strengthening of the solid solution, to enhance the strength and hardness of metallic materials. Precipitation strengthening has significant impact on microstructural features such as precipitate type, size, and distribution that are coordinated by composition and thermomechanical processing. Furthermore, the microstructural features are often associated with the composition, thermal treatment, and precipitation sequence of the processing-structure-property relationship.^[10] All of these factors suggest that hardness belongs to the mechanical properties, which could be highlighted with the microstructure on metallic alloys.^[11]

However, the correlation between hardness of precipitation phases and galvanic current capacity is critically dependent on both the composition and the microstructure. This is developed during casting influenced by chemical elements, thermomechanical processing, and heat treatment.^[7] It is well known that microstructure is essential for the properties of metallic materials. In the case of galvanic materials particularly, the influence of dendrite arm spacing has become related with the presence of galvanic cells or galvanic pairs with the consequence current release during the surface degradation.^[12] In this work, as an alternative of this study, the ability of magnesium as a third alloy component was considered because magnesium is the most active anodic metal in the galvanic series; and the magnesium in this kind of alloys acts as the active anode component if it is in contact with other metals.^[13] Even though the relationship between microstructure and electrochemical dissolution and hardness of AlZnMn-xMg alloys associated with precipitates was poorly studied,^[12,13] Having all this in mind, the present study deals with the microstructural evolution; the improvement in microstructure was done by different atomic combinations

of magnesium alloying under an as-cast condition first, and aging thermal treatment was the second condition to transform the microstructure.

The present investigation concentrates on studying the effects of magnesium addition on the microstructure in as-cast and after ageing treatment. Likewise, we compared it with hardness and electrochemical degradation. The aim of the present study is to understand better the role played by magnesium in the distribution of $(\text{MgZn})_{49}\text{Al}_{32}$ particles, which results in the activation of an anodic process related to the galvanic current and the hardness of the AlZnMn-xMg alloy. This study includes microstructural examination, electrochemical calculations, and hardness tests.

Microstructure was studied using scanning electron microscopy with an energy-dispersive X-ray spectroscopy analysis and X-ray diffraction. The electrochemical behavior is investigated by open-circuit potential measurements. We found that effectively the thermal treatment and high magnesium content are the principal factors for structural changes that increase the electrochemical degradation with current capacity delivered and also with the hardness results. The electrochemical test reveals the susceptibility of the AlZnMg-xMg alloy with the artificial ageing in addition to the present quantity of the $(\text{MgZn})_{49}\text{Al}_{32}$ phase.

EXPERIMENTAL PROCEDURE

Synthesis of AlZnMn-xMg Alloys and Thermal Treatment

The alloy was processed by stoichiometrically mixing the pieces of commercially available elemental Al, Zn, and Mg (ingots 99.8%). The alloy was prepared by melting Al (660°C), Zn (420°C), and Mg (650°C) ingot pieces in a high-alumina crucible, kept in a vacuum induction furnace. To identify the influence of magnesium on the passivation of aluminum alloy, alloying with eight different compositions of Mg was considered. Furthermore, a careful control of the concentrations of manganese as trace impurities is required. The reaction of manganese with iron impurities promoted a precipitation distributed in grain boundaries.^[14,15]

The molten alloy is reached at 700°C above the liquidus temperature. While a constant flux of argon was used to avoid the contact with the environment and the oxidation losses during the pour; 3 wt% Al and 7 wt% Zn were taken in excess to the required amount of these constituents. The liquid bath was stirred for 10 min in order to obtain a uniform distribution of Zn, Mg, Mn, and Fe. The AlZnMn-xMg melt was conventionally poured into a steel mold to form an ingot of 20 mm×50 mm×70 mm. The resultant ingot was machined to eliminate the structure formed by the direct contact with the mold wall. The first liquid alloy in contact with the mold wall possesses one of the

Table 1 Chemical composition of AlZnMn-xMg alloy given in wt%

Metallic alloy	Mg	Zn/Mn	Mn
Mg alloy -1	3.96	16.81 ± 0.03619	0.3189

*The alloys are balanced with aluminum. Trace elements are in the range of 0.1281625 ± 0.01512621.

most dominant microstructures, produced in cast form, the wall-equiaxed structure.

In order to know the chemical composition and distribution of the constituent phases as main factors responsible for the electrochemical degradation behavior, Table 1 shows the nominal chemical composition of AlZnMn-xMg alloys, obtained by optical emission spectroscopy, using an SPECTROLAB spectrometer Model X8-WINDOWS LAX with 15 analytical channels, which operates under a Microsoft Windows environment. These results were the average of five analyses in different regions of the specimens.

Precipitation Sequence by Thermal Treatment Processing

For the purpose of investigating the effect of precipitates, magnesium, and heat treatment on the microstructure of the eight AlZnMn-xMg alloys, samples of 100 g were cut from the cast ingot. These samples were heat treated at 450°C for 5 h, allowing that all solute atoms from each soluble phase enrich the solid solution. Then quenching was carried out using water at room temperature to attain supersaturation. The homogenized samples were then artificially aged at 400°C for 1 h, in order to start the precipitation process, characterized by increasing solubility with increasing temperature.

Homogenized process is sensitive to the selected trace elements and microalloying elements, which can change the process and/or kinetics of precipitation in many hardenable alloys by ageing.^[14] Frequently, the aging heat treatment involves the formation of finely dispersed precipitates from the SSSs in order to increase the hardening/strengthening of the alloy system.

Metallographic Study

In order to know the imaging structure of the alloy and the microstructural features, the as-cast and aged samples

were sectioned longitudinally at mild-width using a band saw. Just one side was made ready for microstructural characterization by the standard technique. It begun through the grinding with metallographic paper of SiC up to #1000, after that a mechanical polishing is done with 0.5 and 0.05 mm alumina powder. Based on the chemical etching, which is controlled by the electrolytic action between surface areas at different potentials, the surface alloys it is etching by Keller's reagent.^[15] The Keller reagent contained 5 mL of HNO₃, 3 mL of HCl, 2 mL of HF, and 190 ml of H₂O to the etch of metallic alloy at room temperature for 15 s.

Morphological Characterization

Structural investigations were carried out with a Siemens D5000 X-ray diffractometer (XRD) with a power of 40 kV accelerating voltage × 30 mA current, using Cu tube of K α line radiation: $\lambda=0.15406$ nm and a diffracting beam graphic monochromator. The XRD patterns were recorded in the 2 θ range of 30°–90° (step size 0.02°, time per step 0.6 s), besides the evaluation of diffractograms were made by DIFFRACT/AC software.

The AlZnMn-xMg microstructures were observed by Olympus PM-G3 optic microscopy and a Steroscan 440 scanning electron microscope (SEM) using backscattered electron imaging (SEM) operated at 20 kV. SEM combined with energy dispersive X-ray spectroscopy (EDS) OXFORD Isis 300 was used to analyze microstructural modifications as well as to identify the elemental composition of the phases formed.

Mechanical Testing

In order to observe the AlZnMn-xMg ability to resist plastic deformation from a standard source, the Vickers hardness was measured. The measurement was done with a microhardness tester INSTRON model 210013. Values were obtained on the cross sections of the samples using a load of 2 N for 10 s, and at least 10 impressions were recorded of each sample. The resulting hardness reading depends on the load and the area of the permanent pyramid impression. Hardness values were averaged excluding the maximum and the minimum values, then the experimental error was estimated.

Performance Evaluation

In order to know how many ampere-hours of protective current will be available for each unit-weight of AlZnMn-xMg alloys, the galvanic performances were evaluated by a short-term electrochemical test.^[16] The working electrodes, also called anodes in an oxidation reaction with dimension of 10 mm² width×50 mm length, were prepared from AlZnMn-xMg ingots of as-cast and aged condition. All the specimens were polished with 1200 emery paper then

decreased in acetone, and finally washed thoroughly in double distilled water. The working electrode used for each test was mounted in a specially designed electrochemical cell using the three-electrode system and was connected electrochemically to a galvanostat DC current source. A saturated calomel electrode (SCE, $E=+0.242$ V saturated) was the reference electrode, used as half-cell. The reference electrode controls the working electrode potential as well as a reference from the potentials measured. An auxiliary electrode, from electrochemically inert platinum wire, was used as a counter electrode. It functions as cathode (in half-cell) and also passes all the current needed to balance the reaction at the working electrode. A sheet of carbon steel served as the cathode, while, for the electrolytic test solution synthetic seawater was used. This solution was prepared with sodium chloride analytical-grade reagent and distilled water with an initial pH of 8.3 according to ASTM D1141.^[17]

The test anode and cathode were galvanically coupled together at different current density levels (0.4, 1.5, and 4.0), and immersed in the electrolytic solution for 3 days. The anodic current density, mA/cm², was applied during a 24-h period. The samples were taken out to be cleaned by ASTM G 31 standard practice. The anodes were then rinsed with distilled water, dried by blowing hot air, and weighed in order to obtain their weight loss. The weight of the AlZnMn-xMg was measured before and after the immersion. From the actual weight loss measured, the capacity and theoretical current or total charge to be produced by the alloy could be calculated. The anode efficiency (η) was calculated by the actual ampere-hours delivered by AlZnMg-xMg alloys between the theoretical ampere-hours calculated from weight loss of AlZnMn-xMg alloys.

RESULTS AND DISCUSSION

X-Ray Diffraction

The qualitative analysis of diffraction patterns shown in Fig. 1 belongs to as-cast and ageing condition of the AlZnMn-xMg alloys. The determination of atomic conformation is in an effort to relate the composition alloys with electrochemical degradation and also the anodic efficiency.

The X-rays enable record of what happens to the crystal structure through the process of casting and heating samples of an AlZnMn-xMg material. Figure 1a,b shows that the alloys in as-cast and aged condition was composed of α -Al solid solution and (MgZn)₄₉Al₃₂ phase, also called precipitates of τ -phase particles. These two phases appear when the Mg addition is up to 5.49%. The microscopy scanning examination provided additional confirmation of these two phases. The first phase is a simple face-centered cubic (fcc) of α -Al solid solution rich in aluminum with an estimated lattice parameter $a = 0.4049$ nm. The second crystalline phase is a body-centered cubic (bcc) of (MgZn)₄₉Al₃₂. This phase is also called τ -Al₂Mg₃Zn₃ with lattice parameter $a = 0.1416 \pm 0.03$ nm, Pearson symbol cI 162, and space group Im-3 (No. 204), which is based on a periodic arrangement of icosahedral Berman clusters.^[18] Furthermore, the presence of α -Al solid solution and (MgZn)₄₉Al₃₂ phases is according to the ternary phase diagram^[19] merely when the magnesium content is upper to 4.89 at%. For the case of less atomic concentration in magnesium, the intermediate τ -phase magnesium-rich (Mg₂Al₃ or Mg₅Al₈) with cubic cell $a = 2.8239$ nm, space group Fd-3m was not detected. Even though the magnesium crystal structure is hexagonal close-packed (hcp) like

Fig. 1 Precipitation evolution on Al-Mg matrix + Zn/Mn ratio with oxidation and applied load interaction
Source: Acknowledgement to Engineering, 2012, 4, 590–597.

zinc element, the incorporation of magnesium atoms into the Al-Zn alloy is entrapped in α -Al solid solution. The magnesium-rich phase reduces the mechanical properties of castings^[8] and is treated as an unwanted microstructural component for the AlZnMn-xMg alloys.

In addition, the X-ray inspection is unable to distinguish one phase precipitation as can we deduce from Fig. 1a. The progressive shifting of diffraction peaks (530) and (100) suggests a precipitation for the other phase. These peaks belong to the $(\text{MgZn})_{49}\text{Al}_{32}$ phase. The shifting of diffraction is from 2θ angles of 36.71° – 35.3° , and 8.80° – 6.58° , respectively, which was formed up to 7.33% Mg content. The magnesium content is 1.38 times more than the atomic percentage of zinc, which is nearly constant for all the alloys.

X-ray diffractometry follows the structural changes of AlZnMn-xMg alloys produced by casting process and the alloys with an age thermal treatment. The X-ray diffractograms for samples in as-cast and aged conditions show that $(\text{MgZn})_{49}\text{Al}_{32}$ phase precipitates formed in our alloys with high Mg addition. But there are few reflections of the $(\text{MgZn})_{49}\text{Al}_{32}$ phase precipitates for samples with low Mg as shown in Fig. 1a. These observations demonstrate that the formation of the $(\text{MgZn})_{49}\text{Al}_{32}$ phase particles was promoted through the high Mg addition and the aging treatment condition. Previously, it was assumed that the fact that 7000 series aluminum alloys have a strong trend for preferential precipitation during the subsequent aging process.^[8]

With the X-ray diffraction measurement, we found the atomic-structure differences between the two phases in AlZnMn-xMg alloys. But it is apparent also from inspection of Fig. 1a that the relative intensities for the (111) reflection of the α -Al, which is a rich-aluminum solid solution with crystalline structure fcc, are much higher than the other peaks. This higher relative intensity indicates the presence of a texture, which was developed during the casting operation. It should be mentioned that the XRD intensities was influenced too by the phase content, the crystallite size, lattice strain, and degree of crystallinity.^[20]

During the heat treatment, an atomic reordering of the aluminum matrix appears toward a preferential direction of the planes (220) and (311) as it can be observed in Fig. 1b. The variations in intensity and small displacements of the diffraction angle have their origins from the variations in composition of the alloy probably due to the formation of an SSS enriched by solute atoms like magnesium and zinc. These were the primary elements of alloy, also called second elements associated with a metal to form an alloy.

Microstructure Characterization

The first result showed that the $(\text{MgZn})_{49}\text{Al}_{32}$ phases were formed by two routes: the first route as a product of the solidification process when the Mg addition is up 5.49% Mg and the second route by the aging precipitation process in the composition range of 7.33%–11.53% at.% Mg. The other phase in the Al-alloys under study was the α -Al, which was formed through the solidification route mainly. All the alloys contain α -Al with a dendritic structure developed by the combination of thermal and constitutional undercooling. It is well known that a solidification structure depends strongly on the solidification conditions. The representative microstructure can be observed from Fig. 2a,b under as-cast condition. These two figures reveal the presence of an equiaxed morphology structure. Considering four of the AlZnMnMg alloys, which a composition from 7.33% to 11.53% at. Mg, the primary solidification for α -Al solid solution was followed by the eutectic solidification of $\alpha + \tau$ - $(\text{MgZn})_{49}\text{Al}_{32}$ phase, these phases can be observed preferentially in Fig. 2b, which corresponds to phase with white color.

In addition, it is reported in the work of Rafi, Ram, Phanikumar, and Rao^[2] that the lamellar eutectic structure is derived from the decomposition of the α' phase by the following cellular reaction at 488.85°C :

The stable phase $(\text{MgZn})_{49}\text{Al}_{32}$ was observed homogeneously dispersed on the Al-matrix with a geometry of rods. The precipitates shown in Fig. 3a were observed

under as-cast condition and were modified with heat treatment. It can be observed from Fig. 3a that the dendritic structure was broken down and showed a quasibinary eutectic mixture. This apparent eutectic structure was formed by aluminum with $(\text{MgZn})_{49}\text{Al}_{32}$, which was always observed along the grain boundaries of the primary α -Al matrix in aging condition alloy. In the eutectic region, the light contrast corresponds to the phase $(\text{MgZn})_{49}\text{Al}_{32}$. While dark contrast matches the α -Al phase (Fig. 3b), Al-matrix or solid solution rich in aluminum possesses the same *fcc* crystalline structure of aluminum. The literature on alloys^[9,10] of the type studied in this work points out that the solidification equilibrium involves the existence of two phases. One of them is an aluminum-based α -solid solution and the other phase is the τ -($\text{MgZn})_{49}\text{Al}_{32}$. Taking account of the last phase, it has a variable composition around the $\text{Al}_2\text{Mg}_3\text{Zn}_3$ compound, which is considered a non-stoichiometrically intermetallic phase. These intermetallic particles were the second phase that dominant the feature of AlZnMn-xMg microstructures.

Previous work^[21] related the magnesium content with the hardness on an Al-alloy. Evidently, the hardness property is directly connected with the semicoherent and coherent precipitates rich in magnesium. The effect of coherency or semi-coherency second phase, between matrix alpha-aluminum is effectively to impede the dislocation motion and get a hard material. In our case, the precipitate $(\text{MgZn})_{49}\text{Al}_{32}$ and the solid solution of the matrix alloy has the bcc and fcc crystal structure, respectively. The precipitate has a different crystalline lattice spacing that the matrix material forming a connection between the hardness and crystallographic structure between these principal actors.

Another related effect could be the atomic size of alloying elements, because zinc and magnesium were smaller and larger, respectively, than aluminum.^[4] In addition, the presence of $(\text{MgZn})_{49}\text{Al}_{32}$ precipitates was also associated with the galvanic efficiency. That was attributable to the difference in the electrical potential between these precipitates and the matrix. The precipitates allow galvanic activity to continue. It could be considered that the second phase avoids the polarization of the alloys. The precipitates

or the second phase could cause the breakdown of the alumina oxide film.

Hardness Vickers

Microhardness curves from the alloys in as-cast and aging condition are shown in Fig. 4a. The α -Al structure with aging treatment is 8% harder than the surrounding Al-matrix in as-cast alloys. Indeed, the average Vickers hardness measured inside the Al-matrix for as-cast structure is 83.65 HV, whereas the Al-matrix for aging is 91.81 HV. These values emphasize the influence of the $(\text{MgZn})_{49}\text{Al}_{32}$ particles inside the matrix. It can be seen from Fig. 4 the higher point from the alloy added with 5.49% Mg. This alloy has a significantly hardening.

Electrochemical Performance

In Fig. 4b was showed the electrochemical performance throughout the efficiency for this alloy, which was developed at 1.0 vol% $(\text{MgZn})_{49}\text{Al}_{32}$ -phase particles. The peak efficiency was achieved after 4.89% Mg addition. The efficiency curve for as-cast condition shows the similar behavior: the high peak was reached when $(\text{MgZn})_{49}\text{Al}_{32}$ -phase is equal to 1.0 vol%. It is clear that aging treatment enhances the hardness and also the efficiency, when the Mg addition does not exceed 5.49%. It means that the phase $(\text{MgZn})_{49}\text{Al}_{32}$ increases due to the formation of quasi-binary eutectic structure (α -Al+ $(\text{MgZn})_{49}\text{Al}_{32}$). While the α -matrix decreases and also its distribution of $(\text{MgZn})_{49}\text{Al}_{32}$ precipitates.

These results emphasize that the precipitates on the matrix activate the surface of the alloy. The activated surface influenced the electrochemical efficiency when it breaks down the oxide film. This passive oxide over-layer formed in air covered the surface of the AlZnMn-xMg alloy. The efficiency was greater when the initial attack was present for the intermetallic compounds distributed in the matrix. However, the intergranular eutectic phase begins to dissolve it, and this intergranular corrosion was stronger than the $(\text{MgZn})_{49}\text{Al}_{32}$ phase.

Fig. 4 The hardness and anode efficiency plotted against τ -(MgZn)₄₉Al₃₂ phase curves for the alloys AlZnMn-xMg in as-cast and aged condition

Source: Acknowledgement to Engineering, 2012, 4, 590–597.

CONCLUSION

According to the effects of magnesium addition as a third alloying element on the chemical composition of AlZnMnMg, it was related to the microstructure and galvanic efficiency of the alloys modified with magnesium, and the following conclusions were obtained:

The precipitation of (MgZn)₄₉Al₃₂ particles depends on the magnesium addition, aging condition, and the quantity of the eutectic phase formation.

The addition of Mg in just 5.49 at.% to the aging AlZnMn alloy clearly increases the peak efficiency as galvanic material and generates the 1.0 vol% of (MgZn)₄₉Al₃₂ precipitates.

For magnesium content of more than 5.49% with aging condition the eutectic phase increases more than (MgZn)₄₉Al₃₂ precipitates, and the efficiency of the alloy decreases, while for low magnesium content the (MgZn)₄₉Al₃₂ phase was poor such as efficiency.

A galvanic degradation performance as high as 81% was achieved with magnesium plus aging treatment on AlZnMn-xMg alloy that activation process depends on the amount of (MgZn)₄₉Al₃₂ particles deposited at the Al-matrix surface.

Microstructure and Properties of Friction Stir Welded Aluminum Alloys

Izabela Kalembe and Stanisław Dymek

Academy of Mining and Metallurgy, Krakow, Poland

Abstract

Aluminium alloy 7136 belongs to the Al–Zn–Mg–Cu group of aluminium alloys strengthened by precipitation. These alloys offer very good properties, i.e. high strength combined with good corrosion resistance, which makes them suitable for aerospace applications. The limited range of applications of these alloys is due to problems associated with their welding. The Al–Zn–Mg–Cu alloys are classified as non-weldable. The aim of this study was to determine the quality and properties of friction stir welded (FSW) joints of alloy 7136-T76. This article presents the results of a detailed study into the microstructure and mechanical properties of FSW welds. The paper demonstrates that the FSW method is suitable for joining Al–Zn–Mg–Cu alloys. The FSW joints are of good quality and high mechanical properties. Tests of joints created at various tool rotation speeds have shown that joints of suitable quality, in terms of microstructure and properties, can be obtained for a relatively wide range of process parameters. The tool rotation speeds applied during the welding process did not have a significant influence on the quality of the welds.

Keywords: Friction stir welding (FSW); Grain boundaries; Microstructure; Onion ring structure; Thermoplastic zone.

INTRODUCTION

Aluminium alloys are commonly used in aircraft construction. Due to their properties, they are an attractive material for applications in which the main requirement is high strength-to-density ratio. This allows designing durable lightweight structures. The increasing demands of designers as well as competition from other materials (e.g. composites) necessitate the development of advanced aluminium alloys with higher strength, better corrosion properties, low density, etc. Such materials include the aluminium alloy 7136 produced by Universal Alloy Corporation. The greatest disadvantage of aluminium is considered to be the low mechanical properties of its joints, which is why aluminium alloys, particularly those strengthened by precipitation, which include alloy 7136, are considered to be difficult to weld or non-weldable.^[1,2]

The ability to implement new alloys is associated with lowering production costs of components and their assembly. For 7xxx alloys, because of the inability to weld such alloys using conventional welding techniques, owing to their unsuitable microstructure after solidification and porosity in the joint area, the development of methods for joining these alloys is particularly important. One of the latest technologies is the friction stir welding

(FSW) method. Unlike traditional methods, the FSW method does not include the liquid metal phase. The joining process is performed at a much lower temperature than for conventional methods, there is no melting of material and additionally the process is environmentally friendly.^[3,4]

The FSW method is the subject of many studies. In Poland, the development of this methodology has carried on over several years at the Institute of Welding in Gliwice^[5–7] and in Krakow at the PAN Institute of Metallurgy and Materials Science, in collaboration with the University of Education,^[8,9] but due to the scale of the problem, the research is limited to only a few or several alloys.

The FSW process consists of the introduction of a rotating shaft (the tip of a specially designed tool) between the touching edges of the bonded plates and moving it along the line of contact. The heat emitted during this process softens the material, and the moving and rotating tool forces the mixing of the material of the joined plates. The accompanying significant plastic deformation causes a change in the microstructure of the joint.^[3,4]

The aim of this study was to analyse the effect of FSW process conditions on the microstructure and properties of weld joints of alloy 7136.

SUBJECT MATTER AND RESEARCH METHODOLOGY

The subjects of this study were joints of plates of aluminium alloy 7136-T76 created by FSW. The chemical composition of alloy 7136 is shown in Table 1. The standard heat treatment of this alloy (T76) consists of supersaturation from temperature 471°C and two-step ageing: for a period of 24 h at temperature 1218°C and for 9 h at temperature 157°C. Such heat treatment provides high strength combined with good resistance to creep and layer corrosion.

Plates of alloy 7136 with a thickness of 6.35 mm were joined by butt FSW. The welding process was performed at the Edison Welding Institute in Columbus, Ohio, USA. The tool used in the process consisted of a spiral resistance ring and a threaded cone-shaped mandrel. The welding was performed with the following parameters: tool advance speed of 2.1 mm/s, pressure of the resistance ring on the material 26.7 kN and tool rotation speeds of 175, 250 and 400 rpm.

The mechanical properties (hardness measurement and tensile test) and the microstructure of the obtained joints have been analysed. The hardness measurements were performed using the Vickers method on a cross-section perpendicular to the direction of welding. The force applied by the indenter was 9.81 N for 10 s. The distance between measurement points was 1 mm. Samples of the native material (cut perpendicular and parallel to the direction of extrusion) and samples after FSW welding were subjected to a tensile test. The samples of the welded material were cut in such a manner that the stretching axis was perpendicular to the weld and the weld was in the middle of the measurement length of the sample. Samples cut lengthwise along the weld, containing only the weld material, were also subjected to the test.

The examination of the microstructure was performed using light microscopy and scanning electron microscopy (SEM). Samples for metallographic examination were prepared from a cross-section of the joint. The cut samples were pre-sanded and subjected to electrolyte polishing and etching. The SEM method was used for fractographic examination and for electron back-scattered diffraction (EBSD) analysis – an analysis utilizing EBSD. The EBSD analysis provided information about the nature of the grain boundaries.

TEST RESULTS

Quality of joints

The quality of FSW welded joints is influenced by the parameters of the process, i.e. the tool rotation speed, the welding speed and the clamping force.^[5] In this study,

joints created at different rotation speeds have been subjected to testing; the welding speed and the clamping force were constant. Figure 1 shows the macrostructure of these joints with marked characteristic zones occurring in all joints made by FSW.^[3–10]

The different tool rotation speeds used in the experiment (175, 250 and 400 rpm) allowed uniform joints to be obtained. The joints did not contain any nonconformities (pores, cracks). With the increase in rotational speed of the tool, only a change in the structure and shape of the weld was observed. For the lowest tested speed of 175 rpm, the weld is narrower and different in shape from weld joints obtained at higher speeds. This is due to the fact that the rotational speed directly affects the amount of heat generated and the mandrel plays the dominant role here. With the increase in the rotational speed of the tool, the amount of heat generated by the resistance ring increases. The macro photographs of the joints made at speeds of 250 and 400 rpm show the weld widening at the surface, which cannot be seen for the speed of 175 rpm.

A characteristic feature of the joints is the *onion rings structure*, usually present in the nucleus of the weld. In welds of alloy 7136, there was no clear, distinctive nucleus visible in other aluminium alloys welded by FSW.^[5–10] Despite the lack of a clear nucleus in the lower part of the weld, faint traces of the characteristic structure of FSW joints can still be seen, i.e. the presence of onion rings. With the increase in the rotational speed of the tool, such weld structure becomes more pronounced. The formation of the onion rings structure is associated with the complex flow of material during the process. A significant influence on the presence of said structure is the heat generated during the process, the amount of which depends on the parameters of the process.^[11] It is assumed that the ratio of rotational speed to welding speed is an indicator of the amount of heat generated.^[12] In the case of the analysed joints formed at different rotational speeds (the welding speed was constant), the ratio of rotational speed to welding speed was higher for the joints welded at higher speeds. Thus, more heat was generated in the joint created at higher speed. More heat input can cause a turbulent flow of material around the tool due to an excess of plasticized material underneath the resistance ring, resulting in a non-uniform microstructure of the weld, e.g. in the form of onion rings.

Mechanical properties of joints

Figure 2 presents the hardness profiles for joints made at speeds: 175, 250 and 400 rpm.

Each curve allows identification of the central area, which corresponds to the width of the weld. Moving outwards

Table 1 Chemical composition of aluminium alloy 7136

Element	Zn	Mg	Cu	Zr	Fe	Si	Ti	Mn	Cr	Ni	Al
%wt.	7.94	1.99	1.93	0.149	0.065	0.048	0.028	0.016	0.018	0.021	Rest

Fig. 1 Macrostructure of joints of alloy 7136 created with different rotation speeds: (a) 175 rpm, (b) 250 rpm and (c) 400 rpm, SCP – thermoplastic zone, HAZ

Fig. 2 Profiles of hardness distribution in FSW welded joints of alloy 7136 created with different rotational speeds

from the centre, the curve falls within the thermo-plastic zone, reaching its minimum (approx. 120–140 HV) in the heat-affected zone (HAZ), and then gradually returns to the level of hardness of the native material (approx. 200 HV). The smallest decrease in hardness in the HAZ is observed in the joint made with the lowest speed, i.e. 175 rpm. All the hardness curves have the shape of the letter W, characteristic to FSW joints, as observed in most heat treated aluminium alloys.^[4,9,10]

On the basis of the presented hardness profiles, it can be seen that an increase in the rotational speed results in the minima of the curve moving away from the centre of the weld. The higher the rotational speed, the further away the HAZ area with the lowest hardness from the axis of the weld.

Table 2 summarizes the results of tensile tests for samples of the native material, samples with weld joints created at different tool rotation speeds and samples cut along the weld. Samples of alloy 7136, cut both in the direction of extrusion and across it, show tensile strength of more than 635 MPa and a yield strength in excess of 607 MPa.

Samples of weld material have lower tensile strength R_m compared to the samples of native material as well as lower yield point $R_{0.2}$, by approx. 30% and 40%, respectively. A comparison of elongation shows that the elongation of samples with weld joints is less than half that of the native material. The average sample elongation is 5%. Considering the elongation of the weld itself, it was noted that it reaches a higher value than the elongation of the native metal. The weld is very plastic ($A < 14\%$) and also has relatively high strength properties.

The tested joints were created at different tool rotation speeds. However, there was no linear relationship between the speed and the properties of the joints (Table 2). The tensile strength, yield strength and elongation of samples cut across the welds created at different speeds showed similar values.

Strength test samples with joints always fractured on the trailing side of the weld, in the area corresponding to the lowest hardness, at the boundary between the thermoplastic zone and the HAZ. This means that the mechanical properties of the joint are not the same on both sides of the weld – they are worse on the trailing side of the weld compared to the leading side. The crack occurred by shearing. The fracture was of ductile character (Fig. 3).

Microstructure of joints

The obtained results of mechanical properties of the joint can be directly related to its microstructure, namely to the presence of areas of different microstructure within the joint. Transverse hardness profiles are an important starting point to interpret the changes that occur during welding (Fig. 2). These profiles allow the identification of individual zones of the joint (Fig. 1). The obtained FSW joints show a change in the microstructure of their cross-sections typical to FSW welding.^[3–10] Specific areas of the joint have been identified, i.e. the weld, the thermoplastic zone, the HAZ (Fig. 4) and the native material.

The zones vary in size and shape of the grain. These differences arise from the different thermoplastic history of the individual areas. The weld has a relatively homogeneous microstructure characterized by small uniaxial grains with a diameter of approx. 6 mm. This microstructure is the result of substantial plastic deformation

Table 2 The results of tensile strength test

Sample	Tensile strength, R_m (MPa)	Yield strength, $R_{0.2}$ (MPa)	Elongation, A (%)	Efficiency (%)
Native material (L ^a)	641	614	10.5	–
Native material (LT ^b)	635	607	10.9	–

combined with the physical flow of material around the mandrel (stirring) and a significant increase in temperature. The thermoplastic zone is characterized by grains significantly larger and elongated. The areas in the immediate vicinity of the weld are subjected to considerable strain; however, the material in this zone is not stirred. This zone is characterized by the gradient of the strain present in this area as well as the temperature gradient. In contrast, the grain size of the HAZ is similar to the grain size of the native material. The HAZ is the area in which no plastic deformation occurs. The microstructure here is only affected by the temperature.

Figure 4 shows the difference in microstructure on the leading side and the trailing side of the joint. The leading side of the weld is characterized by a distinct boundary which separates the fine-grained area from the area of more elongated grain. In contrast, there is no clear boundary on the trailing side. The microstructure is more complex. Here, there is a gradual transition from the weld micro-structure to the microstructure of thermoplastic zone.

In addition to the grain size, there are also significant differences in the distribution of disorientation of grain boundaries in the analysed areas. Using the EBSD method, grain boundaries distribution maps have been obtained for the weld and the thermoplastic zone on the leading and trailing side (Fig. 5). Within the weld, most of the grain boundaries are large-angled.

The content of individual grain boundaries in each area has been presented in the form of a histogram (Fig. 6). In the thermoplastic zone, a high content of small angle boundaries ($2\text{--}20^\circ$) was observed. The thermoplastic zone on the leading side shows a high frequency of small angle boundaries ($<8^\circ$), while the trailing side shows a higher frequency of medium angle boundaries ($8\text{--}30^\circ$). The weld is dominated by grain boundaries with disorientation angle of $22\text{--}60^\circ$.

An analysis of the microstructure justifies the mechanical properties of friction-welded alloys. Test samples of the weld also have higher yield strength and higher tensile strength compared to samples cut perpendicular to the joint. This suggests that the part of the weld material most vulnerable to damage is the material on the outside

Fig. 5 Maps of the distribution of grain boundaries: lighter lines – small-angle boundaries (disorientation angle $<15^\circ$), dark lines – high-angle boundaries (disorientation angle $>15^\circ$), (a) leading side and (b) trailing side

Fig. 6 Histogram of grain boundaries distribution in the weld and the thermoplastic zone on the leading and trailing side

of the weld, on the trailing side, where the hardness values are the lowest, and where the breaking of the sample occurs. The samples breaking on the trailing side of the weld during the tensile test is a common phenomenon that has been repeatedly discussed in studies on FSW welded joints of aluminium alloys.^[10,13,14] A partial explanation for this behaviour may be the different distribution of large-angle and small-angle grain boundaries on the leading and trailing sides of the weld. The density of small-angle grain boundaries is higher on the trailing side. This can facilitate the process of deformation and thereby contribute to the decrease in hardness.

CONCLUSIONS

The FSW technique is suitable for joining components of 7136. The obtained joints are characterized by the absence of discontinuities in the form of pores or cracks as well as by good mechanical properties.

Tests of joints created at various tool rotation speeds (175, 250 and 400 rpm) have shown that joints of suitable quality, in terms of microstructure and properties, can be obtained for a relatively wide range of process parameters. The tool rotation speeds applied during the welding process did not have a significant influence on the quality of the welds. For all tested tool rotation speeds, it was possible to obtain homogeneous joints without visible defects and with similar mechanical properties.

Strength test samples with welds always crack on the trailing side, in the area of minimum hardness (HAZ near the boundary of the thermoplastic zone).

There is a difference in the deformation and material flow on the leading and trailing sides. This is confirmed by microstructural observations, the distribution of disorientation angle of grain boundaries and hardness measurements.

The weld has a homogeneous fine-grained microstructure with no clear nucleus.

Abstract

Aluminum alloys are light materials with high strength-to-weight ratio, corrosion resistance, and excellent formability. Due to these advantages, they are widely used in many industrial applications such as fabrication of aeroplanes, automobiles, ships, and architectural structures. Many fabrication parameters, such as alloy composition, casting and solidification conditions, strain rate, and ageing conditions, strongly affect the microstructural features such as morphology of phases, solute-dislocation interactions, as well as size and volume fraction of strengthening precipitates, and therefore determine the mechanical properties especially yield strength. This chapter probes microstructural optimization of aluminum alloys and the relationship between their microstructures and yield strength, with emphases on recent progress in microstructural modification of Al-Si alloys, yield strength modeling of dynamic strain ageing in Al-Mg alloys, and modeling of precipitate strengthening in Al-Mg-Si(-Cu) alloys.

Keywords: CALPHAD; Morphology; Phase field; Simulation; Strengthening; Volume fraction.

INTRODUCTION

Although Al was first produced in the pure form in 1825 by Hans Christian Ørsted,^[1,2] it had seldom been widely used in the 19th century. As is known to all, pure Al is very light (2.7 g/cm³, 1/3 of steel in weight) and corrosion resistant; however, it is quite soft compared to tool steel, with 7–11 MPa^[3] versus ~1400 MPa^[4,5] in yield strength. To meet the requirements of applications in industries desiring for light and corrosion-resistant materials, such as automobile, aircraft, and building industries, its strength needs to be improved as well.

In 1901, Alfred Wilms discovered the age-strengthening effect of an Al-3.5–5.5 wt% Cu-Mg-Mn (Mg, Mn < 1 wt%) alloy. The alloy, later named Duralumin, was measured to increase in hardness during storage at room temperature for several days after quenching.^[6,7] Since then, various methods such as solute strengthening, deformation, and precipitation strengthening have been applied in combination to improve the strength of Al alloys. Nowadays, the yield strength of a typical Al-Zn-Mg-Cu alloy can reach ~850 MPa,^[8] corresponding to a strength/weight ratio of 315 MPa/(g·cm⁻³), which is much larger than that of steel [~174 MPa/(g·cm⁻³)].

Al alloys can be commonly divided into eight series as summarized in Table 1.^[8–21] This chapter mainly focuses

on the three series of alloys widely used in fabrication of lightweight cars: 4XXX Al-Si, 5XXX Al-Mg, and 6XXX Al-Mg-Si(-Cu) alloys. The different microstructural aspects that affect the mechanical properties especially yield strength of Al alloys, such as the modification of structure during casting in Al-Si alloys, the mechanism of solute strengthening and dynamic strain aging (DSA) phenomenon in Al-Mg alloys, and precipitate strengthening in Al-Mg-Si(-Cu) alloys, are introduced. These could act as references for understanding of other series of Al alloys, for example, DSA^[22] and precipitate strengthening^[23] are both important for 7XXX Al-Zn-Mg alloys.

TYPICAL MICROSTRUCTURAL EVOLUTION DURING ALLOY FABRICATION AND THE RELATIONSHIP WITH YIELD STRENGTH

Microstructural Modification during Casting of Al-Si Alloys

As mentioned in Table 1, the most typical cast alloy is Al-Si alloy. The phase diagram^[24,25] of the Al-Si system is given in Fig. 1 with an eutectic reaction at 12.6 wt% Si and 577°C. The eutectic structure is comprised of Al matrix and coarse flake like Si particles^[26] as typically shown in Fig. 2a. The

Table 1 Typical composition (in wt%), fabrication, characteristics, and industrial applications of various series Al alloys

Major elements of series and typical composition	Typical fabrication processes	Characteristics	Typical applications
1XXX series pure Al (e.g., 1050 Al99.5)	Various forming processes, always followed by short and low-temperature (350°C–450°C) annealing.	Excellent corrosion resistance, high ductility, and highly reflective finish; high thermal and electrical conductivities, weldable	Mainly in cases where strength is not important, e.g., packaging, containers, foils, automotive trim, light reflectors, piping, architecture
2XXX series Al-Cu (e.g., 2199 Al-2.6Cu-1.6Li-0.2Mg-0.09Zr-0.3Mn-0.6Zn ^[9])	Casting, homogenization, pre-heat, hot roll, recrystallization, hot roll, recovery, solution, stretch, and artificial aging in a sequence	Density reduction, increases in stiffness, fracture toughness and fatigue crack growth resistance, and enhanced corrosion resistance due to Li addition. Reduced anisotropy in mechanical properties compared to 8090	Third-generation Al-Li alloy for structural parts in aircraft and space applications, e.g., upper wing, lower wing, and fuselage of aeroplanes
3XXX series Al-Mn (e.g., 3003 Al-1.3Mn-0.5Fe-0.1Si)	Casting and homogenization (or continuous casting), rolling/extrusion, annealing ^[10,11]	Relatively high thermal conductivity combined with moderate strength, good formability and corrosion resistance. Non-heat-hardenable	Beverage can, ^[10] automotive heat exchanger ^[12]
4XXX series Al-Si (e.g., F357 Al-7Si-0.65Mg ^[13])	Casting with additions of grain refiners and modifiers, with or without following solution and aging treatments	High fluidity during casting due to the high content of Si, good corrosion resistance, low ductility and formability. Typical cast alloy	Cylinders in autos, ^[14] engine block ^[15]
5XXX series Al-Mg (e.g., 5182 Al-4.3Mg-0.15Si-0.29Mn-0.32Fe ^[16])	Casting and homogenization, hot rolling and (hot) forming, ^[17] with artificial aging for Cu-added alloys.	Capability of high strain strengthening due to the high Mg content, very good formability and corrosion resistance especially in seawater. High-quality anodizing ability and weldability. Low thermal stability	Inner car body parts such as fender, and sometimes also for outer panels; pressure vessels, piping and tubing; ship building and architectural use ^[18]
6XXX series Al-Mg-Si (e.g., Al-0.79Mg-0.60Si-0.70Cu-0.25Fe-0.20Mn-0.05Cr-0.06Ti ^[19])	Casting and homogenization, forming (e.g., hot rolling and cold rolling), solution treatment, pre-aging and/or natural aging, artificial aging	Combination of medium strength, good formability and excellent corrosion resistance; good weldability	Outer panel sheets for cars; ship building and architectural use
7XXX series Al-Zn (e.g., Al-12Zn-3.3Mg-1.1Cu-0.20Mn-0.16Cr ^[8])	Casting, homogenization, rolling, solution treatment, forming, aging ^[20]	Very high yield strength and fatigue strength, relatively poor corrosion resistance, not good weldability	Aeronautical and military highly stressed and high-strength structural components, nuclear applications
8XXX series Al-X (X denotes elements except Cu, Mn, Si, Mg and Zn, e.g., 8090 Al-2.5Li-1.2Cu-0.6Mg-0.1Zr ^[21])	Similar to that of 2199	Similar to 2199 except for the undesirable anisotropy in mechanical properties ^[9]	Second-generation Al-Li alloy for structural parts in aircraft and space applications

All compositions in this chapter are in weight percent unless specified, except for those atomic ratios expressed with subscripts.

molten alloys were usually grain-refined using the combined additions of Al-5Ti-1B master alloy and/or about 0.02% Sr, whereas the morphology of the eutectic Si can be modified into fine fibrous particles by the addition of Sr and careful control of processing parameters^[14,26–28] as displayed in Fig. 2b, leading to reduced sizes and aspect ratio.

Such refinement and modification of eutectic Si are aimed at improving the fracture characteristics during tensile^[29] and compressive^[14] tests and thus elevating the alloy's strength and ductility to higher levels as reported (see Fig. 3). The fracture behavior of unmodified Al-Si alloys is dominated by the particle fracture and particle/matrix

Fig. 1 The Al-Si phase diagram

Source: From Predel.^[25]

debonding. According to Dighe et al.,^[30] large Si particles constitute less than 1% of the population of all Si particles in unmodified Al, but they take a substantial proportion of 45% of the debonded Si particles on the fracture profile. Moreover, particles with higher aspect ratios tend to have a greater proportion of fracture in both unmodified and modified alloys.^[14] In the work of Fat-Halla et al.,^[29] the comparison between the faceted brittle fracture surface of unmodified Al-Si alloy and the fracture surface with smooth silky areas and semi-dimple pattern in the Sr-modified alloy by tensile tests, optical metallography, and scanning electron microscope (SEM) reveals a change from brittle fracture in Si particles to ductile fracture within the Al matrix. They suggest that the fine, rounded/fibrous Si particles would not transmit cracks through the material easily as would coarse flakes of Si do.

Grain refinement and modification can also be achieved by additions of P, Na, and B, or by additions of rare earth elements Sm,^[31] La, Ce, Er, Nd, Sc,^[13] Zr,^[13] Y, and Pr as recently reported. Recently, Eu^[32] was found also effective in modifying the morphology of eutectic Si particles. Besides chemical modification, cooling rate, electric

current,^[33] magnetic field,^[34,35] laser melting,^[36] and microgravity^[37] were reported to be effective in modifying Si morphology.

The prerequisite of knowing how modifiers took effect is knowing the basic forms of nucleation and growth of Si crystals that contain twins inside in most cases. The growth of the newly nucleated Si crystals into twins during solidification of Al-Si alloys under suitable undercooling can be explained by the parallel-twin formation proposed by Fujiwara et al. based on investigations using an SEM with an electron backscattering pattern (EBSP) system,^[38] as schematically shown in Fig. 4. The Si crystal with diamond cubic structure tends to grow along its $\langle 112 \rangle_{\text{Si}}$ direction (i.e., the upward direction in Fig. 4a) and the closest packed plane $\{111\}_{\text{Si}}$, which then becomes the faceted surfaces^[39] and is also the twin plane. The corners formed between facets are preferential sites for Si atom attachment. If an atom has been attached on a facet in a twin relationship, then other attaching atoms follow the established relationship and a layer is formed (see Fig. 4b). Driven by the undercooling, the twin-containing front continues to advance toward the liquid in the lateral growth mode shown in Fig. 4c, and subsequently another twin boundary can be generated as indicated in Fig. 4d, and the corresponding outer reentrant angle is 141° . In this stage, a Si crystal with two twins is generated, which is displayed in Fig. 5a in three dimensions. This reentrant edge (type I) serves as a favorable site for atoms to join compared to the ridge with an angle of 219° , resulting in the rapid growth of a layer along $[112]_{\text{Si}}$ direction. New reentrant edges are formed between the existing twins and the grown layer, leading to the thickening of the layer displayed from Fig. 5b, c. In Fig. 5c, two new reentrant edges of type I are generated, and the above process continues; meanwhile, the growing tip becomes wider. It is noteworthy that there exists another growth shape of $\langle 110 \rangle_{\text{Si}}$ dendrite, which exhibits a narrow tip with a constant width (see Ref.^[40] for more details). Both these two growth shapes of faceted Si dendrites were experimentally

confirmed by *in situ* SEM observations during Si melt cooling and analysis of EBSP.^[40]

Extensive investigations have been conducted in order to elucidate how chemical modifiers took effect during modification of Si particle morphologies. One of the widely accepted mechanisms is the impurity-induced twinning (IIT) mechanism, which assumes modifying elements as adsorbed at $\{111\}$ growth steps of the Si crystal that changes the stacking sequence of Si crystal and induces the formation of new Si twins in multiple $[112]_{\text{Si}}$ growth directions. Another popular mechanism is the restricted growth theory, or poisoning of twin-plane reentrant edge (TPRE) mechanism.^[40,41] In this

mechanism, modifier atoms are believed to be absorbed preferentially at reentrant edges formed between growing Si twins and effectively retard the anisotropic growth of Si twins driven by the TPRE mechanism. In experimental investigations applying transmission electron microscopy (TEM)^[42,43] and three-dimensional atom probe (3DAP),^[28] fine $\text{Al}_2\text{Si}_2\text{X}$ (X=Sr, Eu or Yb) particles were observed. The importance of these particles was also stressed in simulation of microstructural evolutions.^[27] However, these particles cannot be well incorporated in the IIT and poisoning of TPRE mechanisms. The recent experimental observations in the atomic scale by Li et al. on Al-Si alloys modified by Sr,^[43] Na,^[44] and Eu^[44,45] additions revealed that Sr/Na/Eu atoms were attached at TPRE, as well as the intersection of Si facets and respectively twins, as shown in Fig. 6. These observations indicate that Sr addition is responsible for the formation of parallel (by poisoning of TPRE) or multiple (by IIT) Si twins and thus modifies the morphology of eutectic Si. The $\text{Al}_2\text{Si}_2\text{X}$ particles are just caused by solute entrapment during the growth of eutectic Si and do not contribute to the modification as previously believed.

These chemical modifiers have been proven effective to increase both the yield strength and elongation substantially in cast^[31] and T6^[13] states by forming various fine dispersoids such as AlP, $\text{Al}_2\text{Si}_2\text{Sr}$, and $\text{Al}_3(\text{Sc}, \text{Zr})$. For example, in an Al-Si-Mg alloy modified by Sr and Zr, the improvement of yield strength is mainly attributed to microstructural refinement, the promotion of Si spheroidization, and the increase of precipitate strengthening resulting from the synergic effects of Sc and Zr additions.

Microstructural Features during Dynamic Strain Ageing of Al-Mg Alloys

The Al-Mg alloys always contain a high Mg content (e.g., 4.3%^[16]), which provides an increased level of solid-solution strengthening (see Fig. 7). However, in these alloys, another common strengthening mechanism refers to the strong dynamical solute atom–dislocation interaction (SADI) during deformation at suitable ranges of temperatures (e.g., $\sim 60^\circ\text{C}$ – 200°C ^[46]) and strain rates (e.g., $\sim 5 \times 10^{-4}$ – 10^0 s^{-1} for 5083 alloy^[47]), leading to DSA. DSA is caused by the diffusion of solute atoms toward mobile dislocations, which is temporarily impeded at obstacles (particles or forest dislocations). Besides the pinning effect of Mg solutes on moving dislocation by SADI, as the other side of a coin, DSA also brings about negative strain rate sensitivity (nSRS) corresponding to the serrated flow in

stress–strain curve^[48] (see Fig. 8a), inverse temperature dependence of the flow stress,^[46] reduced ductility and formation of Portevin–Le Chatelier (PLC) deformation bands^[48] (see Fig. 8b). In industrial applications, Lüders and PLC bands are among problems that restrict the application of a high-strength (highly alloyed) Al-Mg sheets to only the production of inner parts of autos. The former can be well avoided by keeping the cold rolling reduction at a low level as shown in Fig. 8a and carefully adjusting the annealing conditions;^[48,49] on the other hand, the lack of detailed mechanism of DSA limits the development of surface relief methods. In other words, DSA strongly affects the mechanical behaviors and surface quality of high-strength Al-Mg products; thus, the mechanism concerning the relationship between microstructure evolution and yield strength as well as other mechanical properties during DSA is the subject of many researchers.

To optimize the strengthening effect of Al-Mg alloys due to solute strengthening and DSA and minimize the side effects associated with DSA, it is first necessary to elucidate how DSA occurs, and especially how solute atoms segregate around dislocations. In 1949, Cottrell and Bilby^[50] suggested that solute atoms can diffuse to free dislocations, form atmospheres (i.e., cloud) around dislocations, and anchor them. A sufficiently large force, corresponding to a critical velocity of moving dislocation and thus a critical strain rate, is required to tear the dislocation from the solute atmosphere and thus to allow the dislocation to move freely. This continuum model well predicted the relationship between yield point and temperature in experiments.

However, it is worth mentioning that their model, which is also called the solute drag model by van den Beukel,^[51] assumed a continuous motion of dislocations with a steady velocity and required the solute atoms to diffuse in lattice fast enough to follow the moving dislocations (and pin them), which was demonstrated as unrealistic since bulk diffusion in lattice is too slow to catch up with moving dislocations.

In the work of McCormick^[52] and van den Beukel,^[51] the discontinuous motion of dislocations was proposed to account for DSA phenomena. The model can be described in the following two procedures: (1) a dislocation is impeded at an obstacle such as particle or forest dislocations for a waiting time t_w during which mobile solute atoms diffuse toward the dislocation with the aid of vacancies introduced by deformation, and (2) it has to be thermally surmounted before being able to move easily again in a flight time t_f and reach the next obstacle. A decrease in t_w due to the increase in strain rate would lead to less diffusion and smaller pinning effect of solutes on dislocations, and thus a decrease in flow stress would occur. This phenomenologically explains why nSRS occurs. The increase in temperature exhibits a similar influence, and this is called the inverse temperature dependence (see Fig. 9). The repeated locking and unlocking of mobile dislocations manifest themselves in the stress-strain curve as serrated yielding.

In this model, the diffusion of solute toward dislocations is driven by a differential enthalpy of $p\Delta V$ in which ΔV denotes solute misfit volume and p is the dislocation pressure field given in the form of

$$p(x, y) = \frac{(1 + \nu)\mu b}{3(1 - \nu)\pi} y(x^2 + y^2) \quad (1)$$

in which b denotes the Burgers vector (of an edge dislocation in this case), μ is the shear modulus, ν is Poisson's ratio, and (x, y) is the position relative to the dislocation on the plane normal to it. The change in solute concentration in the dislocation core versus time t is expressed in the following equation:

$$\Delta c^{cont}(t) = c(t) - c_0 = (f - c_0)(1 - e^{-(t/t^*)^n}) \quad (2)$$

with $n=2/3$,

$$t^* = \left(\sqrt{2}b^2/D_b\beta W \right) (f/3c_0)^{3/2} \quad (3)$$

and

$$D_b = 2b^2\nu_0 e^{-\beta\Delta H_b} \quad (4)$$

In these equations, c_0 is the bulk solute concentration, D_b is the bulk solute diffusion coefficient, $W \approx |p(x=0, y=\pm b)|$ is the maximum solute binding energy, $\beta=1/kT$ and $f=c_0 e^{\beta W}/(1+c_0 e^{\beta W})$ is the saturation solute concentration,

Fig. 7 Stress–strain curves of pure Al and Al-Mg alloys exhibiting no serrated flow under certain processing parameters such as low and high temperatures and high strain rates. The symbols represent experimental data, and the lines represent simulated curves by Soare and Curtin et al.^[47]

ΔH_b is the activation enthalpy, and ν_0 is the attempt frequency.

The time-dependent extra strength $\Delta\tau_s(t)$ due to DSA is assumed to follow the form similar to $c(t)$ and thus

$$\Delta\tau_s(t) = \Delta\tau_0 (1 - e^{-(t/t^*)^n}) \quad (5)$$

The waiting time t_w is related to the strain rate in the form of $t_w = \Omega/\dot{\epsilon}$ where $\Omega = b\rho_m/\rho_f^{1/2}$, and ρ_m and ρ_f are densities of mobile and forest dislocations, respectively. By defining $t = t_w = \Omega/\dot{\epsilon}$ and $\epsilon^* = \Omega/t^*$, the relationship between $\Delta\tau_s(\dot{\epsilon})$ and $\dot{\epsilon}$ can be given as follows:

$$\Delta\tau_s(\dot{\epsilon}) = \Delta\tau_0 (1 - e^{-(\epsilon^*/\dot{\epsilon})^n}) \quad (6)$$

where $\Delta\tau_0$, ϵ^* , and n are parameters to be fitted. The nSRS phenomena can be explained according to this phenomenological equation, and a demonstration can be found in the work of Kok et al.^[53] In their work, using Eq. 6 with a homogenized crystal plasticity model, the occurrence of serrated flow and formation of various types of PLC bands in different strain rates have been predicted. Thus, Eq. 6 has been demonstrated as basically correct although with its inherent deficiencies. As pointed out by Curtin et al.,^[54] the large leap from Eqs 2 to 5 and the assumed additive nature of strength assumed in Eqs 5 and 6 lack a solid physical justification; meanwhile, the estimated strength and fitted ϵ^* value exhibit large discrepancies with those derived from experiments.

Later on, the pipe diffusion along forest dislocations instead of lattice diffusion has been proposed by Mulford et al.^[55] to account for the migration of solute atoms toward the junction of an arrested dislocation with the forest

Fig. 8 Plateaus and serrations in load extension curves and corresponding surface markings of an Al-6.5Mg-Mn alloy processed under different strain rates and working conditions. (a) shows the curves with Lüders (marked as “A”) and/or serrated (marked as “B”) yielding, and (b) is corresponding schematic of surface appearances. r is the reduction rate of cold rolling before tension, and $\dot{\epsilon}$ represents strain rate. Note that the difference between ① and ③ in (a) also reveals nSRS, i.e., $m = d(\ln\tau)/d(\ln\dot{\epsilon}) < 0$, with τ the strength

Fig. 9 Inverse temperature dependence of stress between 60°C and 200°C and nSRS in Al-Mg alloys. The two experimental sets for Al-1Mg reveal nSRS

Source: From Horiuchi and Ishikawa.^[46]

dislocations, since the presence of vacancies is not necessary for the occurrence of pipe dislocation. In detail, this model, based on the dislocation arrest theory originally proposed by Sleawyk et al.,^[56] assumes that solute atmospheres around forest dislocations are drained by rapid pipe diffusion (along the dislocation core) to the mobile dislocation during t_w , and it does not depend on relatively slower bulk diffusion to form solute atmospheres around dislocations. In this modified model, the solute atmosphere only needs to pin part of the dislocation line instead of the entire dislocation segment at the forest dislocation junction; thus, less diffusion is needed to form an obstacle that increases its strength with t_w , and an nSRS corresponding to the strain strengthening caused by dislocation–dislocation interaction is well predicted. This model has put a temporary halt to the apparent conflict between diffusion rates, temperature, and strain rate $\dot{\epsilon}$; until recently, the atomistic simulation, by Picu and Zhang et al.,^[57] of activation energies for vacancy formation and vacancy-assisted Mg migration through many diffusion paths in the dislocation core showed that pipe diffusion in the absence of vacancies is still not enough to account for the DSA.

Recently, Curtin et al.^[54] investigated the binding energy between a single substitutional Mg atom and an edge dislocation in Al using molecular statics, as shown in Fig. 10a. The differential binding energy of $\Delta W = 0.13 \pm 0.02$ eV provides a strong thermodynamic driving force for the cross-core solute transport from the compression side below the slip plane of the edge dislocation to the tension side above it. The corresponding average activation enthalpy for transitions from tension side to compression side has been predicted as $\Delta H_c = 0.97$ eV in the work of Picu and Zhang, and is also consistent with the

predictions of Curtin et al., and the value is notably lower than the activation enthalpy $\Delta H_b = 1.20$ eV calculated for bulk diffusion. These results imply a larger thermodynamic driving force and a lower diffusion activation enthalpy relative to regions far away from the dislocation core. The Mg solute distribution around the dislocation after diffusion is simulated on this basis and shown in Fig. 10b.

By incorporating this model with the classic solute drag model, a large amount of experiments on Al–Mg alloys over a range of concentrations and temperatures can be well explained.^[58] For example, in Fig. 7, the stress–strain curves of alloys treated out of the nSRS domain were well predicted, while in Fig. 11, the occurrence of nSRS as well as the inverse temperature dependence of tensile flow stress was well fitted by the model.^[47] Furthermore, this cross-core diffusion mechanism saw its direct experimental verification at the atomic scale very recently in 2015. Aboulfadl et al.,^[59] applying atom probe crystallography,

Fig. 10 Binding energy (in eV) of an Mg substitutional solute and an edge dislocation in Al versus Mg solute position, as well as the Mg concentration after diffusion for a time $D_b t / 2b^2 = 0.18$ at 500 K as computed in a kinetic Monte Carlo model. In (a), positive energies indicate binding which reduces total energy, the difference in binding energy between different positions around the dislocation implies a driving force for solute transport from the compression side to the tension side. Arrows denote flux of solutes around the dislocation core in traditional continuum models. The initial Mg concentration in (b) is 0.05 (green color)

visualized a dislocation in a PLC band formed in an interrupted tensile test, as displayed in Fig. 12. This view reveals the inhomogeneous Mg distribution across the dislocation core as well as the long depletion tail behind it, revealing cross-core diffusion.

It should be noted that the occurrence of β - Al_3Mg_2 intermetallic (also termed as Al_8Mg_5 by some researchers^[48]) compound by the transformation of L (35.6 Mg) $\rightarrow$ α -Al (17.1Mg) + Al_3Mg_2 (36.1 Mg) at 450°C ^[60] restricts the age-strengthening capability of Al-Mg alloys. With the formation of this compound, the effective Mg content in solid solution decreases and the material softens. This compound is found to be very brittle, tends to precipitate along grain boundaries, and thus has no significant particle strengthening effect.^[61] Furthermore, it might induce stress corrosion cracking (SSC) susceptibility in alloys with more than 3% Mg since it is highly anodic. This can be solved by adding Cu into the alloy in a Cu/Mg mass ratio of 0.14–0.29^[62] and introducing artificial ageing at 60°C – 180°C . During aging, the oversaturated Mg

content was absorbed into the formation of precursors of $\text{S-Al}_2\text{MgCu}$ phase, which are GPB zones, S'' and S' in a sequence. Thus, in elevated temperatures, Al-Mg products with Cu additions do not suffer from softening; instead, their strength can be further enhanced, but with compensation in ductility^[63] and possible decrease in corrosion resistance.^[64] It should also be noticed that in Al alloys, for which the strengthening effect mainly comes from precipitates, such as in 6XXX Al-Mg-Si(-Cu), 2XXX Al-Cu, and 8XXX Al-Li alloys, strengthening by forest dislocations is

Fig. 12 Reconstructed 3DAP data containing a dislocation segment from a slice extracted from a PLC band formed during tensile test of an Al-4.3Mg alloy. The dislocation is viewed along its line direction $\langle 114 \rangle$. (a) The dislocation core is slightly decorated by Ga ion during sample preparation (see the golden 1.5 at.% Ga iso-concentration surface). (b) 2D concentration map showing the Mg distribution on both sides of the dislocation. not important,^[47] and thus no apparent DSA phenomenon will occur.

Precipitate Strengthening in Al-Mg-Si(-Cu) Alloys

Fundamentals of Natural Aging and Artificial Aging

In an Al-Mg-Si(-Cu) alloy, age strengthening occurs when the alloy becomes a supersaturated solid solution (SSSS) after being solution heat-treated at a high temperature such as 550°C and directly water quenched. Due to the decrease in solubility of Mg and Si in temperatures lower than 550°C (see Fig. 1 for an example), the solute atoms in the α -Al matrix became supersaturated and thus unstable.^[65] Specifically, at room temperature and artificial aging (i.e., paint-baking in industrial fabrication) temperature of about 180°C, solutes nucleate as fine atomic clusters and/or atomic-scale Guinier–Preston (G.P.) zones.^[66] The process at room temperature is called natural aging. In artificial aging, with the elongation of time, these nuclei evolve into fully coherent, semi-coherent, and incoherent precipitates in a sequence; meanwhile, the precipitates coarsen gradually {Guinier, 1996 #74}. The fully coherent clusters, G.P. zones, and semi-coherent precipitates cause strain fields around them^[67] due to their slight lattice misfit with α -Al. The strain fields together with the remaining solutes in α -Al matrix effectively impede the motion of dislocations and thus strengthen the alloy in different levels. The key microstructural parameters that affect the precipitation strengthening effect are type, size, and number density of precipitates.

Precipitates Formed during Ageing

The compositions, morphological features, lattice parameters, and orientation relationships (with the matrix) of various precipitates reported in literature on Al-Mg-Si(-Cu) alloys, to the best of the authors' knowledge, are summarized in Tables 2^[67–76] and 3.^[76–94] It should be noted that most of the elongated precipitates such as β'' , β' , U1, U2, B', and Q', with various cross-section shapes, are fully coherent with the matrix (i.e., with the same lattice parameter of 0.405 nm) along their growth directions $\langle 001 \rangle_{Al}$. This is also the reason why these precipitates grow into needles, rather than plates, cubes or tapered shapes, and so on.

It is widely accepted that the peak-aged intragranular microstructure of Al-Mg-Si(-Cu) alloys is comprised of atomic cluster, G.P. zones, and β'' precipitates. Due to the limited strengthening effect caused by atomic cluster and G.P. zones, the major strengthening effect is believed to come from β'' . The semi-coherent nature of β'' has been reported in the structure determination research by Zandbergen et al.^[67] and further discussed in our previous work.^[95] It was found that in an Al-Mg-Si alloy, a

grown-up β'' as wide as 5 nm contained a stacking fault inside. The semi-coherent nature and the associated strain fields around the needlelike β'' precipitates in a high number density provide effective impedance against dislocation movement.

Extended researches have been conducted to find out clues to composition optimization of Al-Mg-Si(-Cu) alloys, in the purpose of obtaining the highest paint bake response in the first 30 min at around 180°C. Two items are important for this purpose: (1) the composition of β'' precipitates and (2) how Mg/Si ratio and additions of other elements affect the kinetics of precipitation of β'' . Gupta et al.^[3] reported on the basis of qualitative comparison of TEM images that excess Si added to the assumed optimum composition of Al- $x\%$ Mg₂Si can increase the precipitation kinetics. This can be well understood if one connects the alloy composition with the β'' composition of Mg₅Si₆ by TEM and electron diffraction by Zandbergen et al.,^[4] which was further refined as around Al₂₀Mg₄₂Si₃₈ by 3DAP in the work of Hasting et al.^[75]

Cu additions were reported with also a similar enhancement in precipitation kinetics in the work of Miao et al.,^[71,96] where modification of precipitation sequence was identified. In Cu-free Al-Mg-Si alloys, the widely accepted precipitation sequence is SSSS $\rightarrow$ atomic clusters $\rightarrow$ G.P. zones $\rightarrow$ pre- β'' $\rightarrow$ β'' $\rightarrow$ $\beta'/U1/U2/B'$ $\rightarrow$ β + Si (stable),^[97] while in alloys with Cu, it was modified as SSSS $\rightarrow$ atomic clusters $\rightarrow$ G.P. zones $\rightarrow$ pre- β'' $\rightarrow$ β'' $\rightarrow$ Q' ($+\beta$ + Si) $\rightarrow$ Q ($+\beta$) + Si,^[68,96] in which other Cu-containing precipitates such as C, L, S, QP, and QC might be introduced into overaged microstructures (see Table 3). However, the effect of Cu addition on the structure and composition of β'' precipitates was not investigated until recently in our work.^[98] By applying high-resolution energy-dispersive X-ray (EDX) studies and 3DAP, the Cu enrichment was found in β'' precipitates, and the precipitate composition obtained by 3DAP from the cores of precipitates was Al_{28.6}Mg_{38.7}Si_{26.5}Cu_{5.17}. Furthermore, Cu was found by high-resolution scanning transmission electron microscopy (HRSTEM) (see Fig. 13) mainly enriched in Si₃ sites of the classical Mg₅Si₆ atomic model.

Effect of Solidification on Ageing

The effect of conventional solidification on ageing of Al-Mg-Si(-Cu) alloys was rarely studied in recent years since the constituents of the as-solidified microstructures were usually dissolved and the remaining (e.g., AlFeSi particles) was always undissolvable even in elongated ageing. However, in an Al-Mg-Si-Cu alloy, it was found that the Q phase exhibited a very interesting behavior during solidification–homogenization–ageing.^[99] In the as-solidified microstructure, micron-scale Q (see Fig. 14a) and Si particles were found with volume fractions of 1.14 $\pm$ 0.06% and 0.65 $\pm$ 0.33%. The presence of these particles was confirmed by EDX, high-resolution transmission

Table 2 Summary of the ante- β'' solute aggregates and β'' precipitates in Al-Mg-Si(-Cu) alloys^[68]

Precipitate type	Atomic ratio	Morphology characteristics	Space group and crystal parameters (nm)	Orientation relationships	Other characteristics
Spherical G.P. zones (atomic clusters)	Mg and Si clusters and co-clusters, Mg:Si ratio of ~1:1. ^[68] The Mg:Si ratio is close to that of the alloy composition ^[69]	Fine particles with a size of ~2 nm ^[69]	No distinct structure ^[70]	/	Fully coherent with Al matrix, designated as spherical G.P. zones, not observable by HRTEM ^[68–70]
Platelike G.P. zones	Si/Mg=1.	Platelet along $\{001\}_{Al}$ planes	(f.c.c. L10), $a=0.405$ ^[71]	Elongating along $\langle 100 \rangle_{Al}$ directions	Fine plates of a monolayer in thickness, with a width of about 2.5 nm and a length of less than 30 nm
G.P. zones or nano-precipitates	$Al_{6.4}Mg_2Si_{2.6}$ ^[72]	Short needles along $\langle 001 \rangle_{Al}$, ~5 nm×2 nm×2 nm	Same f.c.c. structure as α -Al		Formed by replacing some Al sites by Mg and Si ^[72]
Pre- β''	$(Al+Mg)_5Si_6$ ^[73]	Short needles along $\langle 001 \rangle_{Al}$, ~10 nm×2 nm×2 nm	The structure resembles that of β'' with different positions for some of the Mg atoms along the needle direction	/	The structure is more similar to the Al matrix than β'' . With the Al replaced by Mg and Si, this phase develops as β'' ^[73]
β'' (G.P.-II zone)	Mg_5Si_6 ^[67] or Mg/Si=1.1 with ~20 at. % Al ^[74]	Needles along $\langle 001 \rangle_{Al}$	C2/m, $a=1.516$, $b=0.405$, $c=0.674$, $\beta=105.3^\circ$ ^[67]	$[100]\beta'' // [230]_{Al}$, $[010]\beta'' // [001]_{Al}$, $[001]\beta'' // [ps >> 10]_{Al}$ ^[67]	Recent research showed that it contains significant level of Al, e.g., ~20 at.%. ^[74] Streaks around the needles caused by its stress field in the Al matrix around it ^[67,74,75]
	Al_3MgSi_6 ^[75]	Needles along $\langle 001 \rangle_{Al}$	P2/m, $a=0.77 \pm 0.02$, $b=0.67 \pm 0.01$, $c=0.203$, $\gamma=75 \pm 0.5^\circ$	$(001)\beta'' // (001)_{Al}$, $[100]\beta'' // [310]_{Al}$ ^[75]

electron microscopy (HRTEM), and/or diffraction and theoretically predicted in Thermo-calc software using the well-established multicomponent multiphase thermodynamic database for Al alloys.^[100] After being homogenized at 550°C for 4 h, only very few Mg_2Si , Si, and AlFeSi particles were observable at the micron-scale, but in higher magnification, the very fine dispersed Q particles with sizes around 30 nm were found. These nano-sized Q particles were then dissolved during ageing for even as short as 10 min. After being aged at 175°C for 8 h, the alloy contained dense fine β'' precipitates and were strengthened to 144 ± 3 HV. This is a hint that if the heat treatments could be well adjusted so that in the homogenized and solution-treated microstructure dense nano-scale Q particles are present while other remains are as few as possible, these Q particles can be quickly dissolved during the initial stage of aging and provide additional solutes to the SSSS for the formation of solute clusters, G.P. zones, and precipitates.

Modeling the Relationship between Microstructure and Yield Strength during Precipitate Strengthening

For qualitative interpretation of the relationship between microstructure and mechanical properties (mainly yield strength) of Al-Mg-Si(-Cu) alloys, the concept that densely distributed fine β'' precipitates in aged microstructures lead to high strength is widely accepted. However, this is not enough because the industrial community desires to clarify the quantitative relationship among composition, processing parameters, and mechanical properties in which microstructure is the bridge between them. The quantitative relationship between microstructure and yield strength is thus the subject of many researchers and were intensively investigated in recent years.

In 2003, Esmaili et al.^[101] proposed a yield strength model for 6111Al-Mg-Si-Cu alloy which divides the yield strength into three parts in the following equation:

$$\sigma_y = \sigma_i + \sigma_{ss} + \sigma_{ppt} \quad (7)$$

where the three parts σ_i , σ_{ss} , and σ_{ppt} denote the strengthening contributions from pure Al, solid solution, and precipitates, respectively. σ_i is believed to be constant and equal to 10 MPa according to experimental data in literature. σ_{ss} is modeled as a function of the amount of solutes in the matrix C_{ss} and is equal to

$$\sigma_{ss} = f_2(C_{ss}) \quad (8)$$

where f_2 is the coefficient, but C_{ss} is dependent on the volume fraction of precipitates since formation of precipitates causes depletion of solutes in the solid-solution matrix. By using relative volume fraction f_r (between 0 and 1

Fig. 15 The proposed relationship between F and r . m , r_{peak} , and F_{peak} are parameters to be fitted, and Γ is the dislocation line tension equal to a constant $0.5Gb^2$ where G is the matrix shear modulus
Source: From Esmaili et al.^[101]

for the initial and peak-aged status) of precipitates with average radius r , Eq. 8 can be rewritten as follows:

$$\sigma_{ss} = \sigma_{0ss} (1 - \alpha f_r)^{2/3} \quad (9)$$

where σ_{0ss} can be derived from experiments as 50 MPa, and α is a tunable parameter ranging between 0 and 1.

The remaining part σ_{ppt} is related to several microstructural parameters, and for the isothermal ageing of as-solution-treated 6111 alloy, it can be simplified as follows:

$$\sigma_{ppt} = MF / (bL) \quad (10)$$

where M is the Taylor factor and b is the magnitude of the Burgers vector, F represents the maximum interaction force between an average-sized precipitate and the dislocation, L is the average spacing between the precipitates which are acting as obstacles to dislocation motion. F and L should be linked to measurable quantities such as r and f . In detail, the relationship between F and r is displayed in Fig. 15 by assuming F is proportional to r^m .^[102]

According to the strong obstacle theory for precipitates, the parameter L can be given as follows:

$$L = (2\pi/f)^{1/2} r \quad (11)$$

Now, Eq. 10 only contains variables f and r . r can be directly obtained by experiments, and f is assumed to follow the Johnson–Mehl–Avrami–Kolmogorov (JMAK) model of

$$f_r = 1 - \exp(-kt^n) \quad (12)$$

with relative volume fraction

$$f_r = f f_{peak} \quad (13)$$

and

$$k = k_0 \exp(-Q/RT) \quad (14)$$

The variables k , n , and f_{peak} are derivable during the calibration of the model in respect of experimental data, i.e., f_r , f_{peak} , and r by isothermal calorimetry and/or TEM.^[19] Finally, σ_{ppt} can be derived as follows:

$$\sigma_{ppt} = \frac{MF_{peak} f_{peak}^{1/2}}{br_{peak} (2\pi)^{1/2} f_r^{1/2}} \quad (15)$$

for under- and peak-aged conditions,

$$\sigma_{ppt} = \frac{MF_{peak} f_{peak}^{1/2}}{br_{peak}^m (2\pi)^{1/2}} r^{m-1} \quad (16)$$

for overaged conditions,

$$\sigma_{ppt} = \frac{M\Gamma f_{peak}^{1/2}}{b(\pi/2)^{1/2}} r^{-1} \quad (17)$$

in conditions with $r \geq r_c$. The comparison between modeling and experiments is quite satisfactory as shown in Fig. 16.

Fig. 16 Comparison between the modeled and experimental results for the yield strength evolution of a solution-treated 6111 Al-Mg-Si-Cu alloy during aging. (a) aged at 160°C and 200°C, (b) aged at 180°C and 220°C
Source: From Esmaili et al.^[101]

Besides, by considering the exothermic dissolution of clusters and endothermic formation of needlelike precipitates during the early stage of ageing of naturally aged 6111 Al-Mg-Si-Cu alloy, Esmaeili et al.^[103] established a kinetic model to describe the concurrent dissolution and precipitation with verifications by isothermal calorimetry and TEM. By incorporating this kinetic model with the above-mentioned yield strength model, the experimental yield strength evolution of naturally aged 6111 Al-Mg-Si-Cu alloy during artificial aging at temperatures 140°C–200°C is well fitted.

The deficiencies of the yield strength model by Esmaeili et al. are apparent. The use of relative volume fraction instead of experimentally determined volume fractions, the oversimplification from needlelike precipitates with length and diameter to objects with only a radius, and the too many parameters to be adjusted according to experimental data reduce the physical validity of the model and make it hardly applicable to another Al-Mg-Si-Cu alloy with another composition.

In 2007, Song et al.^[104] established a model considering the needle shape of precipitates, as well as the different interactions between moving dislocations and precipitates in different size. The average length l and cross-section radius r of precipitates were assumed to be proportional to the square root of ageing time, and the aspect ratio $A=l/r$ was assumed to be constant. Volume fraction of precipitates was a function of A , r , temperature T , and aging time t in the following form. The related equations are

$$l = 2/3A(\beta Dt)^{1/2} \quad (18)$$

$$r = 2/3(\beta Dt)^{1/2} \quad (19)$$

where the growth parameter β is proportional to the supersaturation Ω by

$$\beta = \Omega/pA = (C_0 - C_e) / \left[(C_p - C_e)pA \right] \quad (20)$$

with p being a factor; and:

$$f_v = \frac{2\pi}{A} r^3 L N_0 Z \beta^* \exp\left(-\frac{\Delta G^*}{kT}\right) t \quad (21)$$

In these equations, D is the solute diffusion coefficient in relation to T , L is the Avogadro number, N_0 is the mole per unit volume, Z is the Zeldovich factor, ΔG^* is the critical activation energy for precipitation, and β^* is a parameter to be fitted with regard to the critical radius r^* of precipitates. This model also assumes a maximum volume fraction of precipitates f_{mv} when excess solutes are exhausted, which is similar to the f_{peak} proposed by Esmaeili et al., but is related to composition rather than radius in the following equation:

$$f_{mv} = \frac{2\pi}{A} r_m^3 L N_0 Z \beta^* \exp\left(-\frac{\Delta G^*}{kT}\right) t_m = \frac{C_0 - C_e}{C_p} \quad (22)$$

Furthermore, in Song's model, unlike previous models used for Al-Mg-Si(-Cu) alloys, it was considered that dislocations cut soft shearable precipitates below a critical size r_c and bypass them otherwise. In the cutting mechanism, the strength contribution is divided into three parts, namely order strengthening, coherency strengthening, and modulus strengthening. Order strengthening occurs when the coherent precipitate has a superlattice compared to the disordered solution α -Al matrix, coherency strengthening operates when elastic interaction between strain field of a precipitate and the dislocations occurs, and modulus strengthening is the result of the difference between shear moduli of the matrix and the precipitate. Thus, the total strength increment due to the interaction of dislocation cutting precipitate is

$$\Delta\sigma_{cutting} = \Delta\sigma_{order} + \Delta\sigma_{coherency} + \Delta\sigma_{modulus} \quad (23)$$

where the detailed equation for each part is not given here.

On the other hand, in conditions with $r > r_c$, the strength increment caused by dislocation bypassing mechanism is

$$\Delta\sigma_{bypass} = \frac{0.15Mgb}{2r} (f_v^{1/2} + 1.84f_v + 1.84f_v^{3/2}) \ln\left(\frac{2.632r}{r_0}\right) \quad (24)$$

with r_0 the cut-off radius for calculation of dislocation line tension.

Using Eqs. 23 and 24 and calibration of these equations by experimental l and f_v versus ageing time t , the yield strength evolution of an Al-Mg-Si alloy during aging has been well fitted as displayed in Fig. 17a, and this model can be applied to another alloy aged at a series of temperatures (see Fig. 17b).

Dixit et al.^[105] separate the yield strength of an Al-Zn-Mg-Cu alloy into several parts, i.e., contributions from grain boundary strengthening, solute strengthening, dislocation strengthening, precipitation strengthening, stacking fault strengthening, and modulus strengthening, as follows:

$$\sigma_y = \sigma_{gb} + M \sqrt{\Delta\tau_{ss}^2 + \Delta\tau_D^2 + \Delta\tau_{ppt}^2 + \Delta\tau_{sf}^2 + \Delta\tau_{mod}^2} \quad (25)$$

In the near future, it would be significant and interesting to suitably incorporate the characteristics of the three yield strength models introduced in this section and propose a new model that considers all aspects of strength contributions and change in dislocation-precipitate interaction with precipitate size using less simplifications and less parameters varying from alloy to alloy.

COMPUTATIONAL PREDICTIONS OF EVOLUTION OF MICROSTRUCTURES AND YIELD STRENGTH IN AL ALLOYS

By routine experimental investigations, knowing how all the factors control the precipitation is necessary

Fig. 17 Simulated and experimental yield strength evolution of Al-Mg-Si(-Cu) alloys during aging. (a) shows the evolution of an Al-1.0Mg-0.6Si alloy at 150°C, and (b) shows that of a 6061 alloy aged at four different temperatures

Source: From Song.^[104]

for designing new alloys with desired properties, but it requires a huge amount of research work. In recent years, a possible efficient path toward this summit by coupling theoretical methods such as CALculation of PHase Diagrams (CALPHAD),^[12] multiphase field simulation method,^[106,107] yield strength modeling,^[101] and so on has been probed, which presents materials scientists a bright future of efficiently designing new alloys by simulations of microstructures and mechanical properties.^[108] For example, the CALPHAD approach was demonstrated effective in simulation of microstructural features during homogenization of a 3XXX Al-Mg-Fe-Si alloy, such as alloying elements

in solution, the number density and size distribution of dispersoids, the inhomogeneity of spatial distribution of dispersoids, as well as the type and fraction of intergranular constituent particles.^[12] The multiphase field simulation is based on well-established thermodynamic and kinetic databases, as well as thermophysical properties of phases such as elastic constants, interfacial energies derived from experiments and first-principles calculations. By carefully constructing the model with solid experimental verifications, multiphase field simulation does not require tunable phenomenological parameters varying with alloy composition and heat-treatment temperature. The simulated results can be used for three-dimensionally displaying the microstructural evolution versus time from micron- to nano-scale^[109] (see Fig. 18 for an example), many structural parameters, e.g., grain size, the morphology, spatial distribution, size, and volume fraction of phases, can be obtained, which can be used as the input data for yield strength modeling. Very recently, the development of phase-field crystal methodology has guided researchers in the Al alloy field into the atomic-scale world, and some phenomena during early stage of ageing of Al-Mg-Si(-Cu) such as clustering and formation of G.P. zone have been well simulated with solid experimental verifications.^[110] It is hopeful that with these results considered the clustering phenomena pervasively existing during natural aging, pre-aging or early-stage artificial aging can be better incorporated into the current yield strength models to enhance their rationality, applicability, and accuracy.

CONCLUSION

The chapter focuses on recent progress in the investigation of microstructure–yield strength relationship in aluminum alloys, specifically on microstructural modification of Al-Si alloys, yield strength modeling of DSA in Al-Mg alloys, and precipitate strengthening in Al-Mg-Si(-Cu) alloys. The conclusions are as follows:

1. Chemical modification of Si particle morphology during casting of Al-Si alloys is due to the attachment of solute (e.g., Sr, Na, Eu, and so on) atoms at the TPPE of Si particles, as well as at the

Fig. 18 Simulation of the microstructure evolution as a function of dimensionless time t^* in an Al-2Cu alloy. The simulation size is $\sim 750 \times 750$ nm². The simulated platelike precipitates are θ' . The experimental morphology by TEM is displayed in the right part

intersection of Si facets and respectively twins, which is verified by HRSTEM and 3DAP studies. These findings indicate that the IIT mechanism and poisoning of TPPE mechanism are responsible for morphology modification of Si particles, rather than the occurrence of $\text{Al}_2\text{Si}_2\text{X}$ ($\text{X}=\text{Sr}, \text{Eu}, \text{or Yb}$) dispersed particles.

2. A cross-core model has been established to account for the DSA in Al-Mg alloys. In this model, there is a strong thermodynamic driving force and a lower diffusion activation enthalpy for the cross-core solute transport from the compression side below the slip plane of the edge dislocation to the tension side above it. This finding has been verified by 3DAP and leads to the understanding and modeling of nSRS during DSA.
3. Strengthening effect in Al-Mg-Si(-Cu) alloys is mainly due to the formation of semi-coherent needle-like β'' precipitates that are densely distributed with a fine nano-scale size in the alloy. Yield strength models were established to predict the evolution of yield strength during ageing with the evolution of size and volume fraction of precipitates. A recent model considers different interactions between dislocation and precipitate with different sizes, i.e., cutting and bypassing.
4. Microstructural simulation methods such as CALPHAD and phase-field modeling can hopefully provide reliable microstructural parameters for yield strength modeling, promoting deeper investigation on the relationship between fabrication, microstructure, and yield strength.

Abstract

This article describes concepts of three features of microstructure–properties relationship, first the imaging and formation of nano-particles, then their contribution to hardness, and finally hydrogen embrittlement during fatigue. First, we briefly review the imaging modes in transmission electron microscopy (TEM) for nano-sized precipitates. The next issue is the hardening in Aluminum alloys, which is caused by GP-zones or precipitates, formed at the second step of the annealing process. After homogenization, the peak-hardness can be generally achieved by a few hours of annealing between 120°C and 200°C. Hardness measurements and equal-channel axial pressing (ECAP) showed that even at room temperature the driving force for formation of the particles is so strong that already within one hour of annealing after homogenization a remarkable hardening occurs. The third issue, hydrogen embrittlement, is caused by oxidation of pure Al surfaces produced at the crack tip during fatigue under ambient or wet moisture conditions. The cracks propagate preferentially along the precipitation free zone adjacent to grain boundaries, where hydrogen diffusion is fastest.

Keywords: Annealing; Fatigue properties; Grain boundaries; Hydrogen embrittlement; Mechanical properties; Microstructure; Precipitation; Precipitation-free zone; Transmission electron microscopy.

INTRODUCTION

After Alfred Wilm discovered in 1911^[1] the age-hardenable aluminum alloys, Duralumin has attained large popularity due to its high strength above 400 MPa.^[2] Aluminum alloys are used in aircrafts and automobiles because of their light weight. Aluminum profiles are produced by extrusion processing due to the relatively low melting temperature of aluminum at 670°C. Duralumin is already mentioned in many textbooks as the most pronounced example for precipitation hardening,^[2] including the details of the annealing procedure. Concerning lightweight in the last decade carbon fiber and carbon nanotube (CNT) composites have substituted many parts made from aluminum in the aircraft industry. There is a large market for Al wires, which are transmitting electric energy from power stations to consumers, because aluminum has high electric conductivity. The additive manufacturing using 3D-printers with powder metallurgy and/or laser sintering is forming a new

market for aluminum as structural or functional applications.^[3–6] The relatively low melting temperature of aluminum provides best conditions for equal channel axial pressing (ECAP),^[7,8] a processing method based on severe plastic deformation, gaining more and more interest during the last two decades, because of easy shaping and best homogeneity.

Detailed investigations of age-hardenable Al-alloys occurred around 1980, when high-resolution transmission electron microscopy (HRTEM) with its atomic resolution became available. The development of the HRTEM techniques and the clarification of the sequence of precipitation from GP-zones via coherent to semi-coherent metastable particles occurred both at the same time, and both fields of science triggered each other. In Japan, the Society of Light Metals published numerous reports of micrographs of precipitates in Al-alloys and their influence on properties, see, e.g., the overview articles.^[9,10]

In this article, we review some less known findings on microstructure and mechanical properties of Al–Li and Al–Mg–Zn alloys. We try to provide a comprehensive overview of simple concepts on research on such alloys with different vertical aspects, starting from phase diagram and precipitation forming in the first section, then explaining mechanical properties, and finally fatigue properties and hydrogen embrittlement.

DIRECT IMAGING OF PRECIPITATIONS

Although not recognized when discovered, age-hardened aluminum alloys are in fact nano-materials containing nanometer-size precipitates of intermetallic phases. Fig. 1 confirms that the Al–Li alloy with largest strength contains particles of 40 nm diameter. Here, we review our research findings from around 15 years ago, because understanding of the microstructure means understanding of and gaining insight into the hardening mechanisms. Japanese researchers have investigated almost every alloy, and these data are available as free downloads since around 2008 thanks to open-access initiatives of the Japanese Institute of Metals

and Japanese Institute of Light Metals organizations. For example, one overview article in Japanese language emphasizes the difference to steel: while Fe can solve more than 40 different elements of the periodic table as solid solutions, in the bcc lattice, the choice of hardening elements for Al is limited to Cu, Zn, Mg, Li, Ag, Sc, Si (only in combination with Mg), and rare earth elements, while others are considered as immiscible. By alloying with Li, the specific weight of aircraft alloys could be further reduced from 2.7 to 2.5 kg/m³, but were later beaten by carbon-fiber reinforced plastics (CFRP) and CNT materials with densities of 1.2 kg/m³ and similar strength.

Precipitation is usually first checked by indirect integral methods, such as X-ray diffraction (XRD) or differential scanning calorimetry (DSC). Some DSC results will be shown in the next section, but first the imaging by transmission electron microscopy (TEM) will be described in detail in this section, because direct imaging has many advantages by inspiring the researcher's mind. The imaging techniques of precipitates by TEM will be briefly reviewed in the following section, while other readers may skip to the next section.

Fig. 1 TEM observation of Al–Li precipitates: (a–c) micrographs, (d–h) position of imaging aperture in the diffraction pattern, (i–j) crystal structure of Al (fcc), and Al₃Li (Li₂), (k) Kikuchi map for fcc

All three micrographs of Fig. 1a–c show the same state of an Al–8.6 at-% Li alloy, just taken under different imaging modes in TEM. Imaging of precipitates and other crystal defects by TEM has different levels of complexity. The simplest is the bright field micrograph as shown in Fig. 1a, which is simply an extension of optical microscopy or SEM, since the resolution of both methods is insufficient to resolve precipitates in Al with their nanometer sizes. The pictures are taken with the aperture situated around the incident beam in reciprocal space as shown in Fig. 1d. The analysis by TEM has another advantage, namely that microstructure; chemical composition and crystal structure in reciprocal space can be analyzed at the same time and at the same location of the specimen. The next step in deepening the level of information is illustrated in Fig. 1b, which was taken with the super-lattice reflection of the ordered intermetallic Al_3Li phase. Superlattice reflections are caused by the extension of the lattice parameter, due to ordering as sketched in Fig. 1i compared to the solid solution with random occupancy of crystal sites as seen in Fig. 1h. Hence, in Fig. 1b only the particles appear bright, while the matrix appears dark, as there the imaging conditions for elastic diffraction are not fulfilled. Besides the large 40 nm particles, now even smaller bright spots with the size of about 4 nm are visible.

The more sophisticated HRTEM image in Fig. 1c confirms that the appearances of lattice fringes of large and small particles are the same, because the lattice fringes with double spacing compared to the size of those in the aluminum matrix appear in the same manner. This confirms that both have the same crystal structure. The imaging of lattice planes requires the mode with highest possible resolution, including all possible beams in the aperture as shown in the diffraction pattern for the HRTEM mode in Fig. 1f. For this purpose, the specimen needs to be tilted in a low-index zone axis z , preferentially (100), (111), or (110) as shown in the Kikuchi map in Fig. 1k. In fact, Fig. 1c is taken at $z=(110)$, while the sketches Fig. 1d–f show for simplicity $z=(001)$ as in Ref. [11].

Microscopes for HRTEM possess usually an optimized objective lens with a narrow space for the specimen with limitation in tilting angle. On the other hand, the detailed dislocation analysis as shown in the following section requires large tilting angles, for which a different type of TEM microscope might be favorable. We review briefly the imaging procedure of dislocations. We need to take micrographs under different imaging vectors, which are defined in Fig. 1g as the vector between two excited beams. The procedure requires tilting to a low-index zone axis, for which again the Kikuchi map as in Fig. 1k is a very useful tool. Then tilting of about 10° along a narrow-spaced Kikuchi line is required, which defines the imaging vector $\mathbf{g}$, the normal vector of the lattice planes, which has caused the Kikuchi lines. When taking images with at least three different $\mathbf{g}$ vectors, near at least two different zone axes, a sufficient

amount of data is collected for the Burgers vector analysis according to the $\mathbf{g} \cdot \mathbf{b} = 0$ criterion. This enables us to study the slip systems, slip direction, and dislocation behavior, as illustrated in Fig. 4. An even deeper insight into dislocation structures, especially intersections or reactions between them, can be obtained from the weak beam images as in Fig. 1h. There the imaging is performed with the second diffraction spot out of five, tilted by about 0.5° – 1° perpendicular to the above-mentioned condition for $\mathbf{g} \cdot \mathbf{b}$. For weak beam images, the exposure time becomes rather long and hence, requirements for the operator's skills, microscope and specimen stability increase tremendously.

FORMATION OF PRECIPITATES

In the next section, we briefly review the evaluation of thermodynamical data for the formation of precipitates in an age-hardenable Al–8.6at.% Li alloy. Phase diagrams for the Al–Li alloy system are available based on both experimental and calculated data.^[12] However, when quenching alloys from higher temperatures, vacancies and/or the anisotropy in the formation energy of precipitates may strongly influence the precipitation kinetics.^[13] In previous publications,^[14,15] we have demonstrated a consistent method for investigating the precipitation process in binary Al–Li alloys with several compositions. Such consistent thermodynamic calculations modelling the precipitation kinetics were later published on different Al-alloys 7108.50,^[16,17] and required analysis by at least two of the experimental techniques (XRD, TEM, Atom probe, or DSC), in order to overcome the difficult challenge of characterizing the composition of the solvent species in nano-sized precipitates.^[16] Similar concepts are reported for Al–Zn–Mg alloys,^[18–23] and the third stage of Al–Li alloys containing Cu^[24] for aircraft application.^[25] Precipitation kinetics of Al–Mg–Si, however, are more complicated^[26,27] and are omitted here. We review briefly the required steps as shown in Fig. 2.

At first, we checked in the phase diagram (Fig. 2a) the position of the solidus line for the given alloy composition X . Then, we analyzed the particle distribution according to the TEM image (Fig. 2c), and the heat flow during heating at some constant heating rate based on the so-called DSC thermograms (Fig. 2d). Both figures confirm the bi-modal distribution of particles with no overlapping. From the calculation of the volume fraction by summation over each radius class with its intensity, we could conclude that large particles possess a volume fraction 22 times larger than the smaller ones. This result allowed us to proceed to the next step, the estimation of volume fraction of Al_3Li particles in total. From the calculation according to the lever rule in phase diagram as derived from the formulas in Fig. 2e, we estimated the exact concentration of the solidus lines for Al, $X_{1\infty}$ and $X_{2\infty}$, and that for the δ' particles, X_{1p} and X_{2p} , at two temperatures $T_1=200^\circ\text{C}$ and $T_2=23^\circ\text{C}$, respectively.

By performing this analysis for several alloys with different compositions and/or for different annealing temperatures, we can check the consistency of these calculations, whether all results yield the same solidus line. Furthermore, we can evaluate in Fig. 2g the heat of dissolution for different volume fractions of particles. The fact that small and large particles, both sorts yield the same slope, known as heat of dissolution per volume of 1.35 J/g/vol%, confirms both, consistency and that all particles possess the same Li_2 crystal structure. Baumann and Williams^[28] have determined a value of $\gamma = 14 \text{ mJ/m}^2$ for the interface energy on the basis of the capillarity (Gibbs-Thompson) equation shown in Fig. 2h. The analysis for the critical nucleus size using this value for the specific interface energy yields a critical radius of 1.9 nm. For particles less than 10 nm in diameter, in our case with radius of 2 nm, the strong curvatures of the interfaces cause a nano-size effect, which reduces the interface energy to around 10 mJ/m^2 , when the particles are surrounded by similar material such as saturated Al–Li solid solution matrix. A similar nano-size effect was confirmed by MD-simulations for pores in ceramics,^[29] while free-standing nano-particles would

experience a remarkable increase in interface energy.^[29] The final check according to Fig. 2i is whether the incubation time is consistent with critical nucleus size and diffusion coefficient. The explanation for the rather long incubation time of 1 week for formation of the 2 nm particles is the small amount of low supersaturation and the resulting small driving force. When quenching the alloy from 623 K to room temperature, almost no incubation period is detected in electrical resistivity measurements.^[30] Further details of the precipitate formation can be understood by investigating the three-dimensional microstructural evolution using 3D atom probe analysis.^[31]

As a summary of this section, the quantitative thermodynamical analysis allows some consistency checks, and all parts of the puzzle should fit to each other. The types of particles need to be confirmed by XRD, DSC, and TEM. Volume fraction as a function of temperature measured by TEM and DSC should be consistent to lever rule calculations based on the phase diagram. Critical radius, interface energy, incubation time, and diffusion constant should be consistent to nucleation theory, capillarity, and diffusion equations. It should be emphasized that the size of

already-formed precipitates can be decreased by dislocation cutting in the course of plastic deformation. When the particle size becomes smaller than the critical nucleus size, then the precipitates lose their stability and get dissolved. The deformation-induced dissolution of precipitates has been reported in Refs. [24,32].

The gained information can now be used to influence the microstructure of Al–Li alloys for optimizing properties. Figure 3b shows the original microstructure as described in the section before. If the aim is to grow only the small nano-sized particles, we need to cool slowly from the homogenization temperature. The resulting microstructure is shown in Fig. 3a. The HRTEM images confirm that as expected only small particles grow in this case. We learned that in the usual heat treatment as shown in Fig. 3b only less than 5% of the δ' (Al_3Li) phase precipitated in small particles. Now, all Al_3Li is precipitated in the nanometer-sized particles. As some of them have formed at higher temperatures, they grow a little larger. The mean diameter is about 5 nm compared to 4 nm before. As the thickness of the TEM foil is about 20 nm, some particles lie above each other and on the two-dimensional projection on the film plate, they appear as overlapped, in spite the fact that they are independent. For reducing this image effect, smaller foil thicknesses or STM imaging of the surface could be used. The high volume fraction also causes more particles to be cut at a position that do not represent their largest diameter. Finally, the other extreme is to grow

only the large particles, for which we use the annealing treatment in Fig. 3c, with a slow cooling from 200°C. Indeed, the microstructure in Fig. 3c consists only of the large particles. In fact, the latter microstructure is best for mechanical properties, as discussed in the next section. In order to achieve fast growing, industrial companies produce this alloy by a third short annealing at 100°C after quenching from 200°C.

MECHANICAL PROPERTIES

The mechanism of precipitation hardening has been incorporated in many textbooks^[2] and is briefly summarized here. In most figures, the hardness is shown for Al–Cu and as a function of the annealing time, however, in Fig. 4 we show the hardness as a function of the particle size with our own measurements^[33,34] and others.^[35] In the case of Al–Mg–Si^[36,37] and Al–Zn–Mg^[38–40] alloys similar hardening was reported. Recent approaches with the knowledge database method could correlate Vickers hardness and strength from tensile test data^[40] and other mechanical properties.^[41] The yield strength in solid solution hardening increases with the concentration c of foreign atoms almost linearly ($\sigma \sim c$) for small concentrations. In Al–Cu alloys, the large anisotropy of the interface energy causes the formation of disc-shaped GP-zones, which increase the maximum strength when their sizes are around 0.7 nm.^[31] In Al–Li

Fig. 3 Revised heat treatment schedules for an Al-8.4at.% Li alloy, shown together with the cooling route in the metastable phase diagram, the schematic drawing of particles as the HRTEM micrographs. (a) Growing of 6 nm-sized particles only, (b) bi-modal distribution, (c) 30 nm-sized particles only

with isotropic interface energy only spherical (three-dimensional) particles with radius r are formed. There are two concurrent mechanisms of plastic flow. The first is the cutting mechanism with a hardening effect proportional to the square root of r , and the Orowan by-passing mechanism, where the strength decreases with $\sim 1/r$ for large particles, as shown with dotted line in Fig. 4.

Taking particle cutting as well as by-passing of particles into account, our experimental data points from tensile test experiments as well as LCF experiments^[33,34] fit well to the schematic theoretical curves. The maximum strength in Al–Li alloys can be achieved for 20–40 nm-sized particles, also called the peak-aged state, compared to under-aged or over-aged states when strength is lowered due to too low or too high annealing temperature or time.

There are two more hardening mechanisms, namely fine grain hardening and work hardening.^[42] Strength increases with $1/\sqrt{d}$ according to the Hall–Petch relationship, where d is the grain size. Work hardening describes the fact that dislocations on different slip planes strongly interact with each other. The flow stress increases proportionally to $\sqrt{N}$, the square root of dislocation density N , known as Taylor equation. In Al alloys, the maximum hardness can be achieved by utilizing these hardening mechanisms. With ECAP^[7,8,43] ultra-fine grained (UFG) material can be produced, but it might be vulnerable to recrystallization.

We review now a special phenomenon, a type of plastic instability, called dynamic strain ageing (DSA). It occurs in Al–Li alloys containing ordered precipitates and causes shorter fatigue lifetime and reduced elongation to failure in unidirectional deformation. In the literature, DSA is discussed as a different slip behavior, namely planar slip localized on one slip plane instead of the usual wavy slip.^[33,24,44] Dislocations in materials with fcc structure such as aluminum are usually known for their ability to easily change their slip plane, when a small increase in stress favors the dislocation movement on neighboring slip planes rather than creating another dislocation on the same slip plane. This is the so-called wavy

slip behavior. On the other hand, there is another extreme, planar glide. Once a slip system is activated, it will continue to operate. The transition criterion between two extremes is still not yet clear, but it can be stated that both a high stacking fault energy (SFE) and strong short-range ordering (SRO) lead to planar slip. Additional deformation tests undertaken with Cu–Mn and Ni–Cr alloys have shown that the degree of SRO seems to be the key for planar slip rather than the SFE. In the case of Cu–Mn, the SFE does not change with an increasing Mn content in contrast to the SRO. Consequently, the SRO seems to be dominating to induce planar slip.^[45] Alloys, which deform with planar slip, often show plastic instability, also known in European literature as Portevin–le–Chartier (PLC)-effect. It causes sudden dislocation avalanches, appearing as serrations in the stress–strain curves. This behavior results in a strongly localized strain leading to early crack formation, and therefore these alloys tend to have in general a lower elongation-to-fracture strain. In Al–Li alloys, we found both kinds of slip behavior, depending on the aging condition, planar slip for underaged, and wavy slip for overaged precipitates.^[33]

Before proceeding with fatigue properties, let us finally describe the TEM method to distinguish different dislocation structures.^[24,46] Figure 5 shows three different dislocation structures, which might be mixed up. The first one, Fig. 5a, shows a small angle grain boundary (SAGB) formed by recovery of dislocations by finding a low-energy position through slip on planes perpendicular to the slip plane. In this picture, other dislocations are trapped within the SAGB. When these interactions would continue, it is likely that cell structures are formed. Figure 5b is from a different alloy, but it represents a picture typical for planar slip, as it is also observed in Al–Li alloys with small precipitated particles.^[33] The dislocation analysis showed that all Burgers vectors are the same and lying in the slip plane, in which dislocations pile up at a grain boundary. Figure 5c shows a typical wavy glide behavior on different slip planes, as it is characteristic of slightly overaged Al–Li alloys, which contain only the 40 nm-sized, large-ordered Al_3Li particles. The leading dislocation is trapped by the particles, while the trailing dislocation has overcome the last particle, since it reduces energy. The reason for this attractive force on the trailing dislocation is that particles lying in between both dislocations contain the anti-phase boundaries (APB), caused by the larger Burgers vector in the ordered L_{12} structure according to Fig. 1i and j. The APB energy for Al–Li alloys has been estimated as 160 mJ/m^2 ,^[15,34] and it was concluded that in these underaged alloys the SRO rather than the SFE is responsible for the planar slip.

Fig. 4 Behavior of the yield strength of age-hardenable Al–Li alloys as a function of particle size. The data points represent experimental measurements^[22,23]

FATIGUE PROPERTIES

In fatigue experiments, the microstructure of the alloys must be taken into account, and the situation becomes

Fig. 5 Distinction of different types of dislocation structures: (a) immobile small angle grain boundary, (b) planar slip behavior, (c) wavy glide on different slip planes, and cutting process requiring two dislocations to penetrate the Al_3Li particles
 Source: Reproduction from [35] with © permission from Hanser Publisher.

more complicated. We refer here to results from Al–Zn–Mg alloys^[47–50] with their characteristic precipitation free zones (PFZ) near grain boundaries.^[50,51] High-cycle fatigue (HCF)^[52] occurs almost in a regime without vulnerable plastic deformation. Hence the summation of elastic strain cycles leads to $\varepsilon_e = C_e N_f^{-k_e}$ known as the Basquin equation, that determines the fatigue lifetime N_f . A number of cycles of 10^7 correspond to fatigue which an industrial product experiences within the lifetime of around 10 years. The common knowledge is that fcc alloys such as Al show no endurance fatigue limit and will certainly break after reaching a large number of cycles N_f . In contrary bcc alloys, especially ferritic steels, have an endurance limit and hence can be used for moving parts of an engine. In low-cycle fatigue (LCF),^[52] the criterion of failure is given by the Manson-Coffin equation $\varepsilon_p = C_p N_f^{-k_p}$, and determined by the accumulation of damage that is influenced by the cyclic plastic strain. As the stress amplitudes in tensile and compressive cycles are localized at different positions within the specimen, the damage failure is accumulating with each cycle. Even recrystallization treatments cannot eliminate this kind of damage formed crystal defects. On the other hand, micro-cracks formed usually at the triple junctions of grain boundaries or crystallographic cracks within the grains are usually under-critical and do not propagate. Taking fracture mechanics (FM) into account, the macroscopic crack starts to propagate if a critical stress intensity, called threshold value ΔK_{th} , is reached. The crack propagates in a stable manner as the energy release rate is growing with the crack. During fatigue, numerous micro-cracks are formed at dislocation intersections. They are usually in under-critical condition, because the stress concentrations at their crack tips are far below K_{IC} . In

ceramics, they even partly increase the fracture toughness K_{IC} of a macroscopic crack by additional particles, which cause blunting or increasing the crack path length.

The ordering, such as SRO or Al_3Li particles, within particular alloys influences the dislocation structures; namely it determines whether wavy or planar glide occurs, as mentioned in the section above. The influence on fatigue properties has not yet been completely understood, but a phase diagram for fcc alloys has been proposed and is shown in Fig. 6 as a guideline for further experiments. The y-axis shows the two criteria, which causes the transition from planar to wavy slip, the ordering parameter (SRO) or in some alloys the less pronounced influence of the stacking fault energy (SFE). The x-axis shows the amount of damage and/or the stress amplitude. The dislocation

Fig. 6 Distinction of different dislocation behavior during fatigue experiments. The amount of SRO determines the slip behavior rather than the SFE

structures from TEM observations can be distinguished as cell structures with high density in walls. Persistent slip bands (PSB) are formed as breaks through the sessile dislocation walls and increase in their volume fraction with increasing number of cycles. At strong SRO rather than high stacking fault energy, where planar glide occurs, the fatigue specimens show dislocation groups, with their strongly localized slip behavior, the occurrence of DSA, and early failure. Microstructural analysis of the corresponding fracture surfaces should give more information about the deformation behavior.

Cyclic temperature changes lead to thermal fatigue. By comparing three Al–Mg–Si alloys,^[53] it was found that the alloy A2618–T6 with largest elongation to failure had also the longest lifetime N_f . The material becomes weaker in strength at higher temperature, so its lifetime decreases. In general, the condition for DSA occurrence is considered as the competition between diffusion of solute atoms and dislocation velocity, which occurs at intermediate temperatures. For example, in a study on ductile cast iron, it was found that the DSA phenomenon occurred only in a narrow temperature region.^[54] DSA in this manner was observed and described in Al–Mg solid solution alloys and/or Cu containing Al–Li-based alloys.^[25] On the other hand, plastic instability and strain localization can appear in similar forms without DSA by other mechanisms. This is the case in Al–Li, where the sudden strain increase is caused by avalanche-like triggering of the movement of a large number of dislocations.^[34,35] The mechanical behavior looks similar to DSA, but in fact it is not DSA.

In fatigue experiments, the lifetime is determined by $N_f = N_i + N_p$, where N_i is the number of cycles to form a propagating macroscopic crack that obeys the fracture mechanics and N_p is the number of cycles to propagate the crack until fracture, which means failure of the specimen. Fractography means microscopy of fractured surfaces and can determine the failure mode, or in other words, the mechanism that causes the time limiting step in failure. Four modes in metals can easily be distinguished. Sudden cracks due to high stresses show a river pattern perpendicular to crack propagation, which starts from the location with highest stress. On the contrary, striations in fatigued specimens are formed parallel to the crack front, which propagates more or less

slowly during each cycle according to the above-mentioned PSB's. Cracks formed at creep during relatively high temperature break due to diffusion of material at crack tips and show characteristic round pattern of material flow. Finally, embrittlement of foreign atoms causes weakness of grain boundaries. Hence, their intergranular fracture surface consists of more or less flat grain surfaces.

HYDROGEN EMBRITTLEMENT

The mechanism of hydrogen embrittlement is sketched in Fig. 7. The freshly created surface of a fatigue crack surface will soon be oxidized (Fig. 7a). The oxygen is taken from moisture in the air, while the hydrogen released is absorbed. Hydrogen has the smallest atomic radius, and as in form of an anion, H^+ , it consists only of a proton. Hence, it has the highest diffusion rate among all atoms, and taking polycrystals into account grain boundary diffusion is more than 10^6 times higher than bulk diffusion.

Estimation according to the diffusion equation shows that a macroscopic specimen is already completely penetrated within minutes after hydrogen loading at room temperature. The weakening of metallic grain boundaries (GB) is sketched in Fig. 7b. As they are the weakest parts of a material and possess less bonding partners than a crystal, at a given cyclic stress, hydrogen atoms are able to break interatomic bonds when two ions replace the constituents. A simulated diffusion profile for surface and grain boundary diffusion shows that the concentration in the GB region is about 10 times higher than at a similar position in bulk. This explains an accelerated precipitation kinetic and, consequently, why grain boundary precipitates (GBP) are about 10 times larger than those in bulk. Of course, the amounts of diffused atoms depend on the source. At a constant source (Fig. 7c), the GB-diffusion and size of GBP's would be much smaller.

We have performed fatigue experiments on Al–Zn–Mg^[48,51] bi-crystalline single edge-notched (SEN) specimens, which were cut from strained and recrystallized specimen, so that just one grain boundary lies in the center of the specimen. Then, the notch was placed close to the grain boundary, so that the crack meets it and

Fig. 7 The mechanism of hydrogen embrittlement occurs in three steps: (a) dissociation of water molecules at fatigue crack surfaces, (b) weakening of the intergranular bonds at grain boundaries, (c) fast diffusion along the grain boundary

Fig. 8 TEM micrograph of grain boundaries in Al–Zn–Mg alloy and schematic drawing of precipitates at grain boundaries and bulk, separated by the precipitation free zone; after fatigue in (a) dry air, (b) wet atmosphere, (c,d) reconstructed three-dimensional structure. Source: Fig. 8a,b from^[37] with © permission from Elsevier Publisher.

propagates along the grain boundary. The crack propagation rate da/dN was automatically measured by a DC potential drop method.^[34,48] Three regions of crack growth can be distinguished. At an initial region the cyclic crack propagation rate, da/dN , strongly depends on environment as well as on microstructure and starts after the ΔK value has reached a threshold value, ΔK_{th} . In the middle steady-state region, the crack propagation rate da/dN follows the so-called Paris law $da/dN = C (\Delta K)^n$, where ΔK is the cyclic stress intensity factor that increase per cycle with increasing crack length. In the final region, crack propagation accelerates due to cleavage and void formation. Finally, the stress intensity reaches the K_c -value and instable crack propagation leads to a catastrophic failure.

The TEM investigation could confirm the cyclic plastic zone along both crack surfaces, which extends to a distance of more than 5 μm parallel to the crack surface.^[48] In the case of peak-aged Al–Zn–Mg specimens, we could also see that the crack prefers to run at the precipitation free zone (PFZ),^[51] as it is the weakest part. The diffusion of hydrogen under cyclic loading conditions leads to an enhancement of hydrogen within the GB and, consequently, to a favored crack path. When comparing three specimens, the first one fatigued under dry air, the second one under ambient conditions, and the third one under wet atmosphere, we could find an astonishing structural change in the grain boundary itself as well as in the interface between particle and aluminum matrix. Figure 8a shows the interface region for the specimen fatigued in dry air and (c) its three-dimensional construction. The particle interface appears round, and the grain boundary is twisted like a band without any preferential orientation. The dark line in the PFZ above the grain boundary is a stress contour due to bending strain. In the specimen fatigued under wet atmosphere, however, we observe a strong faceting in the particle interface and a very flat grain boundary plane. The flatness of GB in combination with the hydrogen may even have made a remarkable contribution to the acceleration of the

cyclic crack propagation rate additional to the weakening of the GB bonds (Fig. 7b). Faceting of grain boundaries in the presence of segregation is an often-observed phenomenon related to the anisotropy of interface energy.

CONCLUSION

In this article, we have described the formation, thermodynamics, mechanical properties, fatigue, and crack propagation in selected Al-based alloys, as it was achieved for education purpose. We have focused here on simple concepts in order to encourage basic research in this subject, while modern multi-component alloys became more and more complicated.^[25] While we have focused on direct observation by TEM, recent research requires additionally the combination of several techniques in order to assist the quantitative evaluation of the measurements and provide a deeper insight into the microstructural mechanisms of the phenomena. Understanding the kinetics of the precipitation process and the quantitative relations between the precipitate microstructure and the mechanical behavior allows for more accurate modeling of the processes, leading thereby to predict and achieve optimum material properties. In addition, the microstructure of the precipitation-hardened alloys reflects in the kind of crack propagation that is assisted by hydrogen embrittlement.

Abstract

The precipitation phenomena and their connection with the microstructure of several Al alloys (Al-Cu, Al-Zn, Al-Ag-Zn, Al-Zn-Mg) are described with respect to the concentration and applied thermal treatment. The alloys were rapidly quenched or slowly cooled from a temperature higher than the solid solution temperature to room temperature. Both quenched-aged and slowly cooled alloys were heated from room temperature to the solid solution state and cooled back to room temperature, and their microstructure and precipitation phenomena were followed *in situ* by X-ray powder diffraction, e.g., anisotropy of thermal expansion, phase transitions, thermal hysteresis in phase transitions, change of precipitate shape, partial or complete dissolution of precipitates in the matrix, and formation of solid solution. It has been shown that the microstructure strongly depends on the previous thermal history of the alloys.

Keywords: Al-Ag-Zn alloy; Al-Cu alloy; Al-Zn alloy; Al-Zn-Mg alloy; Electron microscopy; Phase transition; Precipitation in solid; Solid solution; X-ray powder diffraction.

INTRODUCTION

Alloys are intermetallic phases or solid solutions and, as in the case of pure metals, can be in most cases regarded as close-packed crystal structures. Solid solutions are very common in crystalline materials. A solid solution is basically a crystalline phase that can have variable composition; it may be interstitial or substitutional, or have a more complex structure.^[1] The microstructure, precipitation phenomena, and physical and chemical properties of the supersaturated Al alloys, with respect to the composition and aging treatment, have been extensively studied by many authors, applying various techniques. Most of the collected information on the Al-rich alloys, with a special emphasis on Al-Zn alloys, can be found in a comprehensive monograph edited by Löffler,^[2] containing several hundred references. Decomposition of the supersaturated Al alloys, formed at a temperature T_i , higher than the solid solution temperature, T_{ss} , upon quenching to room temperature (RT) (298 K) often starts with the formation of Guinier–Preston zones (GPZ), which are the nuclei for growth of metastable and stable precipitates as the alloy approaches the equilibrium state on aging. For instance, in both Al-Ag and Al-Zn alloys, spherical GPZ are formed followed by

an intermediate precipitation sequence. In case of Al-Ag alloys, the precipitation sequence is spherical GPZ $\rightarrow \gamma'$ (hcp) $\rightarrow \gamma$ (hcp).^[2,3] Information obtained from the studies of binary alloys may help to point out some of the precipitation phenomena which could occur in ternary alloys. However, precipitation in ternary alloys may be so complex, and the extension of the knowledge on binary alloys to ternary ones is usually not straightforward.

This article describes the microstructure, precipitation phenomena, and phase transitions in four groups of aluminum alloys (Al-Cu, Al-Zn, Al-Ag-Zn, Al-Zn-Mg), being supersaturated upon quenching from T_i to RT, depending on the composition and aging treatment. The main experimental techniques used are X-ray powder diffraction (XRD; counter diffractometer having a high-temperature attachment, Debye-Scherrer camera) and transmission electron microscopy (TEM). In high-temperature counter diffractometer studies, a platinum strip (in fact, a Pt alloy) served as a sample holder and a heater; diffraction lines of Pt were used to calibrate the angular scale, utilizing its thermal expansion coefficient ($1.0(2) \times 10^{-5} \text{ K}^{-1}$) measured by the same diffractometer. Appropriate precautions were applied in minimization of systematic aberrations, which influence the positions of diffraction lines, as well

as in manipulation of specimens in order to prevent any transfer of heat to them. The Debye-Scherrer camera enables the recording of high Bragg-angle diffraction lines of Al and its alloys (for $\text{CuK}\alpha$ radiation: $511 + 333$ and 422), which are very useful in accurate determination of unit-cell parameters in cases they are resolved into the spectral doublet $K\alpha_1$ and $K\alpha_2$. The methods applied in interpretation of XRD patterns are described in recent review papers.^[4–6]

Al–Cu ALLOY

The atomic fraction of Cu, $x(\text{Cu})$, in the studied alloy is 0.017. The unit-cell parameter of the alloy quenched from $T_i = 800$ K in water at RT (denoted WQ), i.e., of the phase $\alpha(\text{M/GPZ})$ (the matrix, M, containing GPZ) is 0.22% smaller than that of pure Al, whereas for the slowly cooled (SC) alloy, it is almost equal to that of pure Al (at RT: $Fm3m$, $a(\text{Al}) = 0.40494(1)$ nm). The SC alloy is a two-phase system containing $\alpha(\text{M}/\theta)$ in equilibrium with the (platelike) precipitates of the phase $\theta(I4/mcm$, at RT: $a(\theta) = 0.6063(1)$, $c(\theta) = 0.4872(1)$ nm). The SC alloy shows ~20% broader matrix diffraction lines than the WQ alloy; this may mean that the diffraction line broadening is caused much more by strains in $\alpha(\text{M}/\theta)$ around the precipitates, than by defects introduced during quenching. In the quenched and aged (WQ-aged) alloy, a discontinuous nucleation (precipitation) of the phase θ takes place. In the alloys aged at 425 K (T_1) up to 60 days and at 525 K (T_2) up to 5 h, diffraction lines are split into two components: the high-angle component corresponds to the WQ alloy, whereas the low-angle component corresponds to the SC alloy. As aging proceeds, a gradual transition of the former component into the latter takes place, their interface moving through a crystal grain (Fig. 1).^[7] At early stages of aging, very weak diffraction lines of the intermediate phase θ' are observed. As the aging proceeds, diffraction lines of the phase θ appear and become stronger as the transition process approaches the SC state. From the intensity ratio of the two split components, one can estimate the volume fraction of the matrix having undergone the discontinuous precipitation process. It is of interest to estimate the aging times, t_1 at T_1 and t_2 at T_2 , which correspond to similar shapes of diffraction lines, i.e., to similar volume fractions having undergone the transition. It has been found that $t_2 = 2$ h is equivalent to $t_1 \approx 650$ h, and $t_2 = 4$ h to $t_1 \approx 1320$ h. From the t_1/t_2 ratio, the activation energy for the solute atom diffusion in the alloy has been estimated using the equation:

$$E_D = k \ln(t_1/t_2) / (T_1^{-1} - T_2^{-1}) = 1.1 \text{ eV},$$

where k is the Boltzmann constant. The error of 10 in t_1/t_2 causes the error of 0.01 eV in E_D .^[7]

Al-Zn AND Zn-Al ALLOYS

This review is related to a study of the Al-Zn and Zn-Al alloys, having the following Zn atomic fraction, $x(\text{Zn})$: 0.03, 0.045, 0.08, 0.15, 0.20, 0.24, 0.26, 0.35, 0.38, 0.40, 0.44, 0.48, 0.54, and 0.62. This system is very attractive for studying microstructure and phase transitions, especially in the supersaturated state, with respect to the composition and applied thermal and ageing treatment. Al (fcc) and Zn (hcp) do not form intermetallic phases. The atomic radius of Al is 0.143 nm, whereas that of Zn is 0.134 nm; this difference has a great influence on the microstructure of the Al-Zn and Zn-Al alloys.

The solubility of Zn in Al is the largest among all elements, with a maximum of 67(1) at% at 654(2) K. At RT, the solubility of Zn in Al amounts to 0.85 at%, and that of Al in Zn is smaller than 0.5 at%.^[2,8] Al-Zn or Zn-Al alloys can gradually approach the equilibrium state after rapid quenching and a prolonged aging at, say, RT. This process can be accelerated by aging at an elevated temperature, T_a . In such a state, the alloy contains two phases: α (fcc; matrix, M) containing ~99 at% Al, and β (hexagonal, precipitates), often denoted in literature as $\beta(\text{Zn})$, having ~99.5 at% Zn.^[2,3] It is said that $\alpha(\text{M}/\beta)$ is in equilibrium with $\beta(\text{Zn})$.

The solubility of Zn in Al increases with temperature and the solid solution is formed at T_{ss} , for instance, $T_{ss} = 625$ K for the alloy with $x(\text{Zn}) = 0.395$.^[2,8] After homogenization of the solid solution at T_i higher than T_{ss} , and rapid quenching to RT, the alloy is a supersaturated solid solution at RT. The decomposition of such an unstable alloy takes place immediately after quenching, in nucleation and growth of spherical GPZ, containing ~70 at% Zn.^[2,3] Diffusion of Zn atoms through M, essential in

the formation of GPZ, can be explained by the existence of quenched-in vacancies.^[2] Therefore, the first decomposition state is a two-phase system, at least up to $x(\text{Zn}) \leq 0.44$,^[9,10] consisting of $\alpha(\text{M/GPZ})$ (fcc) in a metastable equilibrium with a dense system of GPZ. During a prolonged aging, at RT or T_a , the decomposition proceeds in a sequence of precipitates; the longest one is as follows: spherical GPZ [fcc, having the diameter up to 3–4 nm and being fully coherent with the host phase, $\alpha(\text{M/GPZ})$]—ellipsoidal GPZ (fcc, fully coherent with the host phase)—rhombohedrally distorted α'_R -precipitates (partially coherent with the host phase, having about ten nanometers in size)—metastable α' [fcc, rich in Zn and being partially coherent with the host phase, $\alpha(\text{M}/\alpha')$]— $\beta(\text{Zn})$ [the final equilibrium precipitates, having micrometer sizes and being incoherent with the host phase, $\alpha(\text{M}/\beta)$]. The sequence of intermediate phases shortens as the aging temperature decreases. For aging at RT, a direct transition of big GPZ into $\beta(\text{Zn})$ precipitates is to be expected. The aging time necessary to approach the equilibrium state, in which $\alpha(\text{M}/\beta)$, depleted in Zn, is in equilibrium with $\beta(\text{Zn})$ precipitates, decreases with the increase of $x(\text{Zn})$ and the aging temperature.^[2,9,10]

Experimental

The alloys were quenched (quenching rate $\sim 10^5$ K/s) from T_i [from 570 to 770 K, depending on $x(\text{Zn})$] in water at RT (specimens WQ) and then aged at RT or at T_a (specimens WQ-aged). The WQ alloys, WQ-aged alloys, as well as slowly heated alloys from RT to T_i and slowly cooled back to RT (specimens SC), were subjected to a gradual change of temperature, from RT to T_i and back to RT; the changes of their microstructure were studied *in situ* by XRD. These XRD studies have shown how accurately aimed experiments may yield useful information, for instance, on the Zn fraction solved/retained in M for different precipitates, P; on the strains occurring at the M/P interface; and on the unit-cell parameters of the supersaturated solid solutions at RT, of the intermediate phase α' , at temperatures of its existence, of the solid solution at T_{ss} , and of the equilibrium phase, $\beta(\text{Zn})$. New data have been obtained on the anisotropy of thermal expansion and the shape change of $\beta(\text{Zn})$ precipitates during thermal treatment and on the temperature hysteresis in the $\beta(\text{Zn}) \rightarrow \alpha'/\alpha' \rightarrow \beta(\text{Zn})$ phase transition. Recent investigations have shown that a correction of the phase diagram, in its middle part, is necessary.^[9–15] Experimental procedures are described in detail in the work of Skoko et al.^[4]

Microstructure of SC Alloys

The SC alloys that are close to the equilibrium state are two-phase systems, $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$, in mutual equilibrium. Diffraction lines of $\alpha(\text{M}/\beta)$ are shifted to higher Bragg angles compared to pure Al, due to Zn retained in $\alpha(\text{M}/\beta)$. The unit-cell parameter of $\alpha(\text{M}/\beta)$ at RT (averaged

among all studied alloys) is independent of $x(\text{Zn})$ amounting $a[\alpha(\text{M}/\beta)] = 0.40445(10)$ nm, which is 0.12% smaller than that of Al, $a(\text{Al})$. Also, the alloys with a small $x(\text{Zn})$ (0.03, 0.045, 0.08), quenched from T_i to RT, aged at 520 K, and very slowly cooled to RT show practically the same value of the unit-cell parameter. Diffraction lines of $\beta(\text{Zn})$ are close to positions of those of pure Zn. The measured unit-cell parameters of $\beta(\text{Zn})$ ($P6_3/mmc$) are $a(\beta) = 0.2665(2)$, $c(\beta) = 0.4947(3)$ nm, and $c(\beta)/a(\beta) = 1.856(3)$ at RT. Diffraction lines of both $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$ are rather sharp, indicating that the annealing of most strains takes place during slow cooling. The orientation relationship between $\beta(\text{Zn})$ and the host $\alpha(\text{M}/\beta)$ is $\{001\}\beta \parallel \{111\}\alpha$, $[110]\beta \parallel [1\bar{1}0]\alpha$.^[2,10]

Microstructure of As-quenched Alloys

In the WQ alloys, decomposition and formation of precipitates take place immediately after quenching. In these alloys, Zn atoms (or clusters of Zn atoms) are not randomly distributed in the host α -phase, due to grain boundaries, dislocations, dislocation loops, stacking faults, vacancies, and Zn-vacancy pairs. This is important for homogeneous (GPZ and $\beta(\text{Zn})$ precipitates) and discontinuous (heterogeneous) ($\beta(\text{Zn})$ precipitates) modes of decomposition.^[2] The first precipitates are GPZ in alloys with $x(\text{Zn}) \leq 0.44$. In the alloys with a higher $x(\text{Zn})$, the decomposition process is very fast and the sequence of precipitates is shortened. The decomposition rate and formation of GPZ also depend on the quenching rate, i.e., on the quenched-in vacancies and aging temperature, which strongly influence the diffusion of Zn atoms inside the host α -phase.^[2,10,11] Characteristic parts of XRD patterns of the WQ alloys with $x(\text{Zn}) = 0.38$ and 0.40, including diffraction lines at low and high Bragg angles, are shown in Fig. 2.^[4,10] For comparison, the corresponding diffraction lines of Al are also shown. Diffraction lines were scanned within 30 min after quenching. These diffraction patterns correspond to two-phase alloys, $\alpha(\text{M/GPZ})$ and a dense system of GPZ, which are in a metastable equilibrium. It is obvious from Fig. 2 that diffraction lines of $\alpha(\text{M/GPZ})$, being rather sharp and resolved in the spectral doublet $K\alpha_1$ and $K\alpha_2$, are shifted to higher Bragg angles in relation to those of Al. That shift increases with $x(\text{Zn})$. The mean diameter of the initially precipitated GPZ in the alloys with $x(\text{Zn}) = 0.24$ is about 2 nm (as found from XRD line broadening and TEM), and the mean separation of adjacent zones is about 8–10 nm.^[9] Therefore, the initial volume fraction of GPZ is $\sim 1\%$ of the alloy volume.^[4] It follows that most of the Zn content in the alloy is solved in $\alpha(\text{M/GPZ})$, causing the shift of its diffraction lines, and only a small fraction of Zn participates in GPZ, despite the fact that GPZ are composed of ~ 70 at% Zn.^[2]

The presence of GPZ in the WQ alloys is manifested as broad humps at the high-angle side of diffraction lines of $\alpha(\text{M/GPZ})$ (Fig. 2). The unit-cell parameter of GPZ is smaller than that of $\alpha(\text{M/GPZ})$ due to a much higher Zn

Fig. 2 Characteristic XRD lines of Al and Al-Zn alloys with $x(\text{Zn}) = 0.38$ and 0.40 (specimens: fine powder). Al was slowly cooled, whereas the Al-Zn alloys were quenched from T_i to RT. XRD lines of the alloys were scanned within 30 min after quenching. Diffraction effect from GPZ is indicated

content, whereas pronounced broadening of GPZ diffraction lines indicates their small sizes. Similar diffraction effects in GPZ were observed by Simerska and Syneček while studying single crystals of Al-Zn alloys.^[16] A dense system of GPZ and dislocation loops in the alloy with $x(\text{Zn}) = 0.08$, quenched and aged at 350 K for 1 day, is shown in a TEM photograph, Fig. 3.^[4,9]

$\beta(\text{Zn})$ is not present in the WQ alloys having $x(\text{Zn}) \leq 0.44$. Its strongest diffraction line, $\beta 101$, is hardly visible in Fig. 2, due to small number of $\beta(\text{Zn})$ precipitates, nucleated during the scan of diffraction pattern.

Characteristic parts of diffraction patterns of the WQ alloy with $x(\text{Zn}) = 0.48$ are shown in Fig. 4.^[4] No diffraction effect could be noticed from GPZ. Instead, strong diffraction lines of $\beta(\text{Zn})$, nucleated immediately after quenching, are present. Diffraction lines of $\alpha(\text{M}/\beta)$ are rather broad, due to strains around $\beta(\text{Zn})$ precipitates; the broadening increases with the Bragg angle (e.g., very broad diffraction lines $\alpha 331$ and $\alpha 422$). For comparison, diffraction lines of the SC alloy, with the same $x(\text{Zn})$, are also shown in Fig. 4. One can notice that diffraction lines at high Bragg angles of the SC alloy are rather sharp and resolved in the spectral doublet $K\alpha_1$ and $K\alpha_2$. The unit-cell parameters of both $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$ of the alloy with $x(\text{Zn}) = 0.48$ differ a little for the WQ and SC alloys due to different Zn contents retained in them, as can be seen in Fig. 4.

The dependence of the unit-cell parameter of the WQ alloys, $a[\alpha(\text{M}/\text{GPZ})]$, on $x(\text{Zn})$ is shown in Fig. 5.^[4,10] These values, averaged over the Debye-Scherrer and counter diffractometer data, indicate that $a[\alpha(\text{M}/\text{GPZ})]$ decreases almost linearly with the increase of $x(\text{Zn})$. This dependence is in a fair agreement with the data given in

Fig. 3 TEM photograph of the Al-Zn alloy with $x(\text{Zn}) = 0.08$, quenched to RT and aged at 350 K for 1 day. Initial GPZ and dislocation loops are visible. A line of zero diffraction contrast across the dislocation loops can be noticed
Source: From Skoko et al.^[4] and Popović et al.^[9]

the literature;^[2] however, the previous literature data were available only for $x(\text{Zn}) < 0.30$.

The dependence shown in Fig. 5 may be explained in terms of the increased fraction of Zn dissolved in $\alpha(\text{M}/\text{GPZ})$ during quenching. For the alloy having $x(\text{Zn}) = 0.44$, $a[\alpha(\text{M}/\text{GPZ})]$ is $\sim 1.0\%$ smaller than that of Al. In the alloys containing a dense system of spherical (or almost spherical) GPZ, coherent with $\alpha(\text{M}/\text{GPZ})$, there should be a continuation of the crystal planes in GPZ into the crystal grains of $\alpha(\text{M}/\text{GPZ})$, strained around GPZ due to the difference in their unit-cell parameters.^[4,9]

Aging of the Supersaturated Solid Solutions

The WQ alloys with $x(\text{Zn}) \leq 0.44$ are two-phase systems (as described above), $\alpha(\text{M}/\text{GPZ}) + \text{GPZ}$. During aging of these alloys, at RT or at T_a , diffraction lines of $\alpha(\text{M}/\text{GPZ})$ gradually decrease in intensity, becoming little broader, but do not change their Bragg angles. At the same time, diffraction lines of $\alpha(\text{M}/\beta)$ appear at Bragg angles close to those of $\alpha(\text{M}/\beta)$ in the SC alloys, whereas diffraction lines of $\beta(\text{Zn})$ appear at Bragg angles very close to those of $\beta(\text{Zn})$ in the SC alloys. Diffraction lines of the two phases, $\alpha(\text{M}/\text{GPZ})$ and $\alpha(\text{M}/\beta)$, having the same indices, are separated as their unit-cell parameters are different due to different Zn fractions retained in them; this separation increases with the initial $x(\text{Zn})$. Diffraction lines of both $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$ practically do not move during the whole aging treatment.^[4,9,10]

GPZ grow in size with aging at first, but, having reached a size of, say, 10 nm and becoming ellipsoidal, they transform to $\beta(\text{Zn})$ precipitates.^[10,17] In parallel to this process, $\beta(\text{Zn})$ precipitates nucleate discontinuously at dislocation loops, grain boundaries, and other defects. For instance, $\beta(\text{Zn})$ precipitates appear in XRD patterns in the alloy with $x(\text{Zn}) = 0.24$ after 24 h of aging at RT.^[9,10] A dense

system of GPZ and initial $\beta(\text{Zn})$ precipitates in the alloy with $x(\text{Zn}) = 0.08$, quenched from T_i to RT and aged for 30 days at 350 K, is shown in Fig. 6.^[9]

At short aging time, diffraction lines of $\alpha(\text{M}/\beta)$ are very broad, because of strains around $\beta(\text{Zn})$ precipitates. As aging proceeds, diffraction lines of $\alpha(\text{M}/\beta)$ become sharper and their intensity increases due to an increase of its volume fraction and a partial annealing of strains around $\beta(\text{Zn})$ precipitates. For a prolonged aging, diffraction lines of $\alpha(\text{M}/\beta)$ finally are partially resolved into the spectral doublet $K\alpha_1$ and $K\alpha_2$. Diffraction lines of $\alpha(\text{M}/\text{GPZ})$ become little broader, due to strains introduced by coarsening of GPZ and, at later stages of aging, due to decreasing of its crystallite size. The number and size of $\beta(\text{Zn})$ precipitates gradually increase with the aging time, as indicated by the increase of diffraction line intensities. The diffraction lines of $\beta(\text{Zn})$ are rather sharp even at very short aging times indicating negligible strains in its crystallites.^[4]

The transition of GPZ into $\beta(\text{Zn})$ precipitates may start with the formation of the hcp sequence (i.e., stacking faults) of the $\{111\}$ planes in GPZ resulting in thin lamellae of the $\beta(\text{Zn})$ structure inside GPZ, with the orientation relationship $\{001\}\beta\parallel\{111\}\text{GPZ}$, in accordance with the one between $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$. From the unit-cell parameters of $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$, the misfit between these two phases is $3c(\beta) - 2a[\alpha(\text{M}/\beta)]^{3/2} \approx 5.5\%$. Due to that rather small misfit, some of the $\{001\}$ planes of thin $\beta(\text{Zn})$ platelets may be continued into $\alpha(\text{M}/\beta)$ as $\{111\}\alpha$ planes, maintaining a certain degree of coherency and causing strains in $\alpha(\text{M}/\beta)$ around $\beta(\text{Zn})$ precipitates. As the aging time proceeds on, $\beta(\text{Zn})$ precipitates grow in size and the mutual coherency along $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$ interfaces is more and more destroyed. Micrometer-sized $\beta(\text{Zn})$ precipitates are not coherent with the host $\alpha(\text{M}/\beta)$.

The transition of the metastable system, $\alpha(\text{M}/\text{GPZ}) + \text{GPZ}$, into a more stable one, $\alpha(\text{M}/\beta) + \beta(\text{Zn})$, in the alloy

with $x(\text{Zn}) = 0.38$ is shown in Fig. 7.^[4,12] Diffraction lines of $\alpha(\text{M}/\text{GPZ})$ and broad humps of GPZ are present 30 min after quenching; for the aging time of 52.5 h at RT, the alloy contains phases $\alpha(\text{M}/\text{GPZ})$, $\alpha(\text{M}/\beta)$, GPZ and $\beta(\text{Zn})$; after a prolonged aging for 35 days at RT, the alloy approaches the equilibrium state, consisting of $\alpha(\text{M}/\beta)$ and $\beta(\text{Zn})$. One can notice the difference in broadening between the corresponding diffraction lines of $\alpha(\text{M}/\text{GPZ})$ and $\alpha(\text{M}/\beta)$. The decomposition rate of the metastable alloy, $\alpha(\text{M}/\text{GPZ}) + \text{GPZ}$, into a more stable one, $\alpha(\text{M}/\beta) + \beta(\text{Zn})$, increases with $x(\text{Zn})$. For the alloy with $x(\text{Zn}) = 0.24$ aged at RT, diffraction line intensities of $\beta(\text{Zn})$ reach a saturation after 3 months, but a gradual sharpening of diffraction lines of $\alpha(\text{M}/\beta)$ is noticed even after 7 months. The corresponding processes for the alloy with $x(\text{Zn}) = 0.44$ last several days. On the contrary, for the alloy with $x(\text{Zn}) = 0.08$, GPZ do not transform to $\beta(\text{Zn})$ at RT. The decomposition process in that alloy is very slow even for aging at 350 K, and the intensities of $\beta(\text{Zn})$ diffraction lines do not reach saturation even after 8 months. For the alloy with $x(\text{Zn}) = 0.24$, the increase of diffraction line intensities of $\beta(\text{Zn})$ is enhanced after 3–4 days, due to a direct transition of GPZ into $\beta(\text{Zn})$; this process takes place in parallel to discontinuously nucleated $\beta(\text{Zn})$ precipitates. Finally, diffraction line intensities of $\beta(\text{Zn})$ approach the values corresponding to the ones of the SC alloys.^[4,10]

Fig. 7 Characteristic XRD lines of the Al-Zn alloy with $x(\text{Zn}) = 0.38$ (specimen: fine powder). The alloy was quenched from T_i to RT and aged at RT for 30 min, 52.5 h, and for 35 days. A gradual transition from the metastable two-phase system, $\alpha(\text{M}/\text{GPZ}) + \text{GPZ}$, into a more stable two-phase system, $\alpha(\text{M}/\beta) + \beta$, can be noticed

Source: From Skoko et al.^[4] and Popović and Gržeta.^[12]

After a prolonged aging of WQ alloys, the Bragg angles of rather sharp diffraction lines of $\alpha(M/\beta)$, being in coexistence with $\beta(Zn)$, are very similar for all studied alloys. It follows that $a[\alpha(M/\beta)]$ is independent on $x(Zn)$, amounting 0.40469(6) nm, being 0.06% smaller than $a(Al)$. For the SC alloys, $a[\alpha(M/\beta)]$ differs from $a(Al)$ for 0.12%. This difference in the unit-cell parameter of the two $\alpha(M/\beta)$ -phases may be explained in terms of different thermal treatments, causing a different fraction of Zn retained in them. A detailed description of the processes taking place during aging of the quenched alloys is given in the work of Popović et al.^[9,10]

Temperature Dependence of the Microstructure of the Quenched-aged and SC Alloys

The WQ-aged and SC alloys have been studied *in situ* by XRD during slow heating from RT to T_i and slow cooling back to RT.^[4,11,12] The temperature dependence of the microstructure of the alloys with $x(Zn) \leq 0.40$ is in a fair accordance with the phase diagram of the Al-Zn system, given in the literature,^[2,8] whereas the one of the alloys with $x(Zn) \geq 0.44$ is not. The results, given in the work of Skoko et al.,^[4] on the temperature behavior of the microstructure of the alloys with $x(Zn) \geq 0.44$ represent a slight modification of statements given in the previous papers.^[11,12]

Al-Zn alloys with $x(Zn) \leq 0.40$

Characteristic parts of XRD patterns of the alloy $x(Zn) = 0.40$ taken at a series of temperatures, including heating and cooling runs, are shown in Fig. 8.^[11] The temperature dependence of the microstructure is similar for both SC and WQ-aged alloys; therefore, the following description of the main observations is related to both thermal treatments.

A gradual increase of temperature causes a decrease in intensities of diffraction lines of both $\alpha(M/\beta)$ and $\beta(Zn)$, due to enhanced vibration amplitudes of the atoms. A shift of diffraction lines toward smaller Bragg angles is observed, due to thermal expansion; this change is linear up to ~ 490 K. At higher temperatures, a partial dissolution of $\beta(Zn)$ in $\alpha(M/\beta)$ takes place; this effect compensates or even reverses the shift of the $\alpha(M/\beta)$ diffraction lines due to thermal expansion, as the Zn atoms are smaller than the Al atoms. The dissolution of $\beta(Zn)$ is manifested in an enhanced decrease of its diffraction line intensities.^[4,11]

As the temperature increases slightly above 550 K, the phase transition $\beta(Zn) \rightarrow \alpha'(fcc)$ takes place. Diffraction lines of $\beta(Zn)$ disappear, whereas at the same time diffraction lines of α' appear at the high-angle side of all α diffraction lines; the phase α is now in a metastable equilibrium with α' and is denoted as $\alpha(M/\alpha')$. Differential scanning calorimetry (DSC) study of the alloy with $x(Zn) = 0.24$ gives the value of 555 K for the phase transition $\beta(Zn) \rightarrow \alpha'$, in line with XRD results.^[4] At 560 K, the

unit-cell parameter of α' is 0.9% smaller than the one of $\alpha(M/\alpha')$, due to a much higher Zn fraction contained in α' . At a given temperature, diffraction line intensities of α' are bigger the higher is $x(Zn)$.^[4,11]

With a further increase of temperature, diffraction lines of $\alpha(M/\alpha')$ and the corresponding diffraction lines of α' move toward each other. These shifts are due to a decrease of the Zn fraction in α' and an increase of the Zn fraction in $\alpha(M/\alpha')$. However, in the temperature interval of the existence of α' , the Bragg angles of its diffraction lines do not depend on $x(Zn)$, and the same is valid for diffraction lines of $\alpha(M/\alpha')$. The diffraction line intensities of α' decrease with the increase of temperature. The solid solution of Zn in Al is formed at $T_{ss} \approx 615$ K for the alloy with $x(Zn) = 0.24$ and at $T_{ss} \approx 655$ K for the alloy with $x(Zn) = 0.40$. Therefore, the sequence of phase transitions during

Fig. 8 Characteristic XRD lines of the Al-Zn alloy (specimen: fine powder) with $x(Zn) = 0.40$ at selected temperatures during the heating and cooling cycles. Prior to XRD study at high temperature, the alloy was quenched from T_i to RT and aged at RT for 11 months

Source: From Popović et al.^[11]

heating of the alloys from RT to T_i is $\alpha(M/\beta) + \beta(Zn) \rightarrow \alpha(M/\alpha') + \alpha' \rightarrow \alpha_{ss}$.^[4]

The phase transition $\beta(Zn) \leftrightarrow \alpha'$ is not observed for the alloy with $x(Zn) \leq 0.08$; for the alloy with $x(Zn) = 0.08$, the solid solution is formed at $T_{ss} \approx 495$ K. As the temperature increases, $\beta(Zn)$ gradually dissolves in $\alpha(M/\beta)$, and its diffraction lines disappear with approaching T_{ss} .^[4,11]

The unit-cell parameter of the solid solution, $a(\alpha_{ss})$, depends on $x(Zn)$; it decreases as $x(Zn)$ increases. The following values of $a(\alpha_{ss})$ are found at 673 K: 0.40925(8), 0.40824(7), and 0.40692(9) nm for $x(Zn) = 0.08, 0.24$, and 0.40, respectively, whereas $a(Al)$ is 0.40952(6) nm at 673 K.

In the temperature interval of its existence, $\beta(Zn)$ exhibits an anisotropy in thermal expansion. It is manifested, e.g., in increased angular separation between diffraction lines $\beta 110$ and $\beta 103$ as the temperature increases. The average thermal expansion coefficients of $\beta(Zn)$ in the interval from RT to 555 K for the studied alloys are $\alpha[110] = 1.1(1) \times 10^{-5} \text{ K}^{-1}$, $\alpha[103] = 5.8(5) \times 10^{-5} \text{ K}^{-1}$, and $\alpha[001] = 8.5(9) \times 10^{-5} \text{ K}^{-1}$.

During the cooling from T_i to RT, the studied alloys undergo the inverse phase transitions, $\alpha_{ss} \rightarrow \alpha' + \alpha(M/\alpha') \rightarrow \beta(Zn) + \alpha(M/\beta)$, but exhibit a temperature hysteresis. For instance, the phase transition $\alpha' \rightarrow \beta(Zn)$ for the alloy with $x(Zn) = 0.24$ takes place at 523 K, i.e., 32 K below the temperature of the transition $\beta(Zn) \rightarrow \alpha'$ in the heating run. According to DSC, the transition $\alpha' \rightarrow \beta(Zn)$ is spread over a much wider temperature interval than the transition $\beta(Zn) \rightarrow \alpha'$. A repeated, second, heating of the same specimen of the alloy with $x(Zn) = 0.24$ shows that the temperature of the phase transition $\beta \rightarrow \alpha'$ is practically similar to that in the first heating. At a given temperature, the Bragg angles of α' diffraction lines in the cooling run are very similar to those in the heating run, not depending on $x(Zn)$. The fractions of Zn in $\beta(Zn)$ and $\alpha(M/\beta)$, and in the α' and $\alpha(M/\alpha')$, while in mutual equilibrium, with respect to the temperature, are discussed in the works of Löffler,^[2] Löffler et al.,^[8] and Popović et al.^[11]

Al-Zn/Zn-Al alloys with $x(Zn) \geq 0.44$

According to the phase diagram, given in the literature,^[2,8] the following phase transitions could be expected:

- For the alloys with $x(Zn) = 0.44, 0.48$, and 0.54: $\alpha(M/\beta) + \beta(Zn) \leftrightarrow \alpha(M/\alpha') + \alpha' \leftrightarrow \alpha_{ss}$
- For the alloy with $x(Zn) = 0.62$: $\alpha(M/\beta) + \beta(Zn) \leftrightarrow \alpha' + \beta(Zn) \leftrightarrow \alpha_{ss}$

However, for the alloys with $x(Zn) = 0.44$ and 0.48 (in which Al is the major element), the following sequence of phase transitions is observed: $\alpha(M/\beta) + \beta(Zn) \leftrightarrow \alpha(M/\alpha', \beta) + \alpha' + \beta \leftrightarrow \alpha_{ss}$.

For the alloys with $x(Zn) 0.54$ and 0.62 (in which Zn is the major element), the following phase transitions are observed: $\alpha(M/\beta) + \beta(Zn) \leftrightarrow \alpha(M/\alpha', \beta) + \alpha' + \beta \leftrightarrow \alpha_{ss}$.^[4,14,15]

Characteristic parts of XRD patterns of the alloy with $x(Zn) = 0.48$ at selected temperatures are shown in Fig. 9,^[4,14] including both the first and second heating and cooling cycles. This alloy was quenched from T_i to RT and aged at RT for 1 week prior to XRD study *in situ* at high temperature.

The unit-cell parameters at RT of $\alpha(M/\beta)$ for both the WQ-aged alloys (0.40469(8) nm) and the SC alloys (0.40445(10) nm) do not depend on $x(Zn)$. These values are the same as the ones for the WQ-aged and SC alloys, respectively, with $x(Zn) \leq 0.40$. Also, the unit-cell parameters of $\beta(Zn)$, in equilibrium with $\alpha(M/\beta)$, are very close to those of pure Zn at RT.

Figures 10–12^[4,14] correspond to the WQ-aged (at RT) alloys and the SC alloys with $x(Zn) = 0.48$, studied *in situ* by XRD at high temperature, showing the temperature dependence of the unit-cell parameter a of the phases α , α' , and α_{ss} , and the temperature dependence of the unit-cell parameters $a(\beta)$ and $c(\beta)$ of $\beta(Zn)$, respectively, during the first heating and cooling cycles. Analogous temperature dependence of the microstructure is observed for the WQ-aged (at RT) alloys in which Zn is the major element.

The temperature dependence of the microstructure of the WQ-aged alloys is rather different from that of the SC alloys, as seen in Figs. 10–12. The two curves, which show that dependence during the first heating from RT to T_i and cooling back to RT, are closer to each other for the SC alloys than for the WQ alloys. The area between the two curves is smaller for the SC alloys than for the WQ alloys. This area slightly increases with the increase of $x(Zn)$. For the WQ alloys, the curves corresponding to the second heating from RT to T_i and the second cooling from T_i to RT are close to the ones of the first cooling from T_i to RT. The curves corresponding to the first heating from RT to T_i deviate much from a linear function. At a given temperature, the difference between the values of a microstructural parameter, found in the heating run and in the cooling run, is smaller for the SC alloys than for the WQ-aged alloys; this difference slightly decreases with the prolonged aging of one and the same WQ-aged alloy.^[4,14]

General features observed in XRD patterns are as follows: As the temperature of a given alloy increases, a decrease of the diffraction line intensities of both $\alpha(M/\beta)$ and $\beta(Zn)$ takes place, due to enhanced vibration amplitudes of the atoms. Thermal expansion manifests in a gradual shift of diffraction lines toward smaller Bragg angles. Thermal expansion of $\beta(Zn)$ is anisotropic as in case of the alloys with $x(Zn) \leq 0.40$. It can be followed, e.g., from the temperature dependence of the separation of neighboring diffraction lines, $\beta 110$ and $\beta 103$ (Fig. 9). An indication of thermal expansion anisotropy may also be a decrease of the saddle intensity between diffraction lines $\beta 110$ and $\beta 103$ (Fig. 9).^[4,14]

The unit-cell parameter, a , of $\alpha(M/\beta)$, for both WQ-aged and SC alloys, increases during the first heating run up to 490–500 K (Fig. 10). At a higher temperature, a partial

Fig. 9 (a)–(i) Characteristic XRD lines of the Al-Zn alloy (specimen: fine powder) with $x(\text{Zn}) = 0.48$, at selected temperatures, including both the first and second heating and cooling cycles. Prior to XRD study at high temperature, the alloy was quenched from T_i to RT and aged at RT for one week. Source: From Skoko et al.^[4] and Skoko and Popović.^[14]

dissolution of $\beta(\text{Zn})$ into $\alpha(\text{M}/\beta)$ takes place. This process compensates and even reverses the change of the unit-cell parameter of $\alpha(\text{M}/\beta)$ due to thermal expansion (Fig. 10), as the Zn atoms are smaller than the Al atoms. In connection with the dissolution of $\beta(\text{Zn})$ in $\alpha(\text{M}/\beta)$, one can observe a change in the shape of $\beta(\text{Zn})$ precipitates with the increase of temperature: the broadening of diffraction lines with $l \neq 0$ (e.g., $\beta 002$, $\beta 103$) increases in relation to broadening of diffraction lines with $l = 0$ (e.g., $\beta 100$, $\beta 110$). $\beta(\text{Zn})$ precipitates become more and more flat, i.e., their dimension along the c -axis decreases as the temperature increases. Zn atoms, which leave $\beta(\text{Zn})$ and dissolve in $\alpha(\text{M}/\beta)$, are dominantly those that form the planes $\beta\{001\}$. This effect is not observed for the alloys having $x(\text{Zn}) \leq 0.40$. The concentration of vacancies in $\beta(\text{Zn})$ increases with temperature, which affects the temperature dependence of its unit-cell parameters in the WQ-aged alloys (Figs. 11 and 12).^[4,14]

As the temperature increases above ~ 555 K, a new phase, α' (fcc), appears in line with the phase diagram. Diffraction lines of α' are located at the high-angle side of the corresponding diffraction lines (having the same

Fig. 10 Temperature dependence of the unit-cell parameter a of the phases α , α' , and α_{ss} in the Al-Zn alloy with $x(\text{Zn}) = 0.48$ during the first heating and cooling cycles. The upper part is related to the WQ alloy aged for 1 week at RT prior to XRD study at high temperature. The lower part is related to the alloy that was slowly cooled to RT prior to XRD study at high temperature. Arrows indicate the sense of temperature change, and vertical bars the estimated standard deviation in a . Source: From Skoko et al.^[4] and Skoko and Popović.^[14]

Miller indices) of the α -phase. The unit-cell parameter, a , of the α' -phase, rich in Zn, is smaller (0.8%–0.9% at 560 K) than the one of the α -phase. It has been found that only a partial transition of $\beta(\text{Zn})$, and probably a partial transition of $\alpha(\text{M}/\beta)$, into α' takes place above 555 K. Therefore, the α -phase is in coexistence (a metastable equilibrium) with both α' and $\beta(\text{Zn})$ (Fig. 9) and is denoted as $\alpha(\text{M}/\alpha', \beta)$.^[4,13–15]

With a further increase of temperature of WQ-aged alloys, the fraction of Zn increases in $\alpha(\text{M}/\alpha', \beta)$, and probably in α' , (Fig. 10, WQ-aged). The Zn atoms leave $\beta(\text{Zn})$, in which the concentration of vacancies increases, compensating the thermal expansion of $\beta(\text{Zn})$ (Figs. 11 and 12, WQ-aged). In the SC alloys, the concentration of vacancies above 555 K is smaller than that in the WQ-aged alloys, and their influence on the thermal expansion is small (Figs. 11 and 12, SC). Diffraction line intensities of α' increase, whereas those of $\beta(\text{Zn})$ and $\alpha(\text{M}/\alpha', \beta)$ decrease.^[4,13–15]

For the alloys with $x(\text{Zn}) = 0.44$ and 0.48 , the solid solution, α_{ss} (fcc), is formed at ~ 880 K for the QW-aged alloys and at ~ 725 K for the SC alloys. The measurement of $a(\alpha_{ss})$ is not so accurate, due to the recrystallization (grain coarsening) effect in the alloys, as the temperature approaches T_{ss} . At 880 K, $a(\alpha_{ss})$ is estimated to be 0.4046(1) and 0.4045(1) nm for the WQ-aged alloys with $x(\text{Zn}) = 0.44$ and 0.48 , respectively. At 725 K, $a(\alpha_{ss})$ is found to be 0.4044(1) and 0.4043(1) nm for the SC alloys with $x(\text{Zn}) = 0.44$ and 0.48 , respectively. The intensity of the diffraction lines of α' decreases in the cooling run more rapidly than it increases in the heating run; at a given temperature, the

Fig. 11 Temperature dependence of the unit-cell parameter a of $\beta(\text{Zn})$ in the Al-Zn alloy with $x(\text{Zn}) = 0.48$, during the first heating and cooling cycles. The upper part is related to the WQ alloy aged at RT for 1 week prior to XRD study at high temperature. Source: From Skoko et al.^[4] and Skoko and Popović.^[14]

intensity is smaller in the cooling run than in the heating run. The opposite effect is noticed for $\beta(\text{Zn})$.^[4,13–15]

On the other hand, for the WQ-aged alloys with $x(\text{Zn}) = 0.54$ and 0.62 , $\alpha(\text{M}/\alpha',\beta)$ disappears at ~ 650 K in the first heating run and α' remains in coexistence with $\beta(\text{Zn})$. Solid solution, α_{ss} (fcc), is formed at ~ 700 K. The value of $a(\alpha_{\text{ss}})$ at 700 K is estimated to be $0.4043(1)$ and $0.4038(1)$ nm for the alloys with $x(\text{Zn}) = 0.54$ and 0.62 , respectively. During the cooling run, a temperature hysteresis in reversal phase transitions is observed. In the second heating run of the same specimen, a temperature delay in phase transitions of several tens of kelvins is found in relation to the first heating run. $\alpha(\text{M}/\alpha',\beta)$ disappears at ~ 720 K, and the solid solution, α_{ss} , is formed at ~ 800 K. During the second cooling run to RT, the microstructure shows a similar dependence on temperature as in the first cooling run and in the second heating run.^[4,13–15]

Diffraction line intensities of $\beta(\text{Zn})$, e.g., in the Al-rich WQ-aged alloys, show three intervals in the first heating run: (1) a small decrease due to enhanced vibration amplitudes of Zn atoms, (2) a steeper decrease (above ~ 500 K) due to dissolution of $\beta(\text{Zn})$ into $\alpha(\text{M}/\beta)$, and (3) a slower

Fig. 12 Temperature dependence of the unit-cell parameter c of $\beta(\text{Zn})$ in the Al-Zn alloy with $x(\text{Zn}) = 0.48$, during the first heating and cooling cycles. The upper part is related to the WQ alloy aged at RT for 1 week prior to XRD study at high temperature. The lower part is related to the alloy that was slowly cooled to RT prior to XRD study at high temperature. Arrows indicate the sense of temperature change, and vertical bars the estimated standard deviation in $c(\beta)$

Source: From Skoko et al.^[4] and Skoko and Popović.^[14]

decrease (above ~ 600 K) toward the formation of solid solution. The behavior during the cooling run is different: after the appearance of $\beta(\text{Zn})$, the intensities of its diffraction lines increase steeply at first, and then this increase is slowed as the temperature decreases toward RT. For the WQ-aged alloys, traces of α' are observed at RT after a complete heating and cooling cycle (Figs. 9g and 10).^[4,13–15]

The value of the unit-cell parameter of the solid solution, $a(\alpha_{\text{ss}})$, for the alloys with $0.44 \leq x(\text{Zn}) \leq 0.62$ does not change linearly with $x(\text{Zn})$, in difference for the alloys with $x(\text{Zn}) \leq 0.40$. The only explanation might be that $a(\alpha_{\text{ss}})$ strongly depends on the previous thermal treatment of the alloy, and that some type of ordering is always present even at the highest temperatures.

The statements described in this review indicate that the phase diagram of the system Al-Zn should be modified in its middle part, where the fractions of Al and Zn are comparable. Moreover, additional studies are needed on the temperature dependence of the microstructure in alloys having even higher $x(\text{Zn})$ than in alloys studied in this review.

Al-Ag-Zn ALLOYS

Al-rich Ag-Zn alloys have not been studied much, even though this is a system in which similar precipitates are

Source: Data from Popović et al.^[23] and Popović et al.^[24]

formed in a wide composition range. The precipitation sequence in these alloys is as follows: GPZ $\rightarrow \epsilon'$ (hcp) $\rightarrow \epsilon$ (hcp); $\alpha(\text{M}/\text{GPZ})$ is strained around GPZ.^[18] The formation of metastable precipitates, ϵ' , was studied by small-angle X-ray scattering (SAXS).^[19] The precipitation processes in several Al-Ag-Zn alloys upon quenching were followed by XRD and TEM.^[20,21] The anomalous SAXS in Al-Ag-Zn alloys was compared to that in Al-Zn alloys.^[22] As an extension of the previous work,^[20,21] the influence of a prolonged aging of the WQ alloys on their microstructure was studied. Also, the microstructure of the same alloys was followed by *in situ* XRD from RT to T_i and back to RT, compared to that of the SC alloys.^[23,24]

Experimental

The Al-Ag-Zn alloys described in this review have the electron-to-atom ratio of 2.9, the purity of the elements being 5N. The chosen Ag-to-Zn ratios (Table 1) might promote a certain stoichiometry of precipitates, e.g., Al_2AgZn or AlAgZn for alloy 3).^[23,24] The melted alloys were cast into copper molds and homogenized at $T_i = 820$ K. Powdered alloys, wrapped in a thin perforated Al foil, were treated at T_i , quenched in water at RT (WQ alloys) and immediately aged at $T_a = 420$ K up to 50 days (WQ-aged alloys). Also, powdered alloys were cooled, inside the furnace, to RT over a week (SC alloys). The WQ-aged alloys, stored for 38 years at RT, were studied *in situ* by XRD from RT to T_i and back to RT.

Microstructure of SC and Quenched-aged Alloys

The values of the unit-cell parameter $a(\alpha)$ for the SC and WQ alloys are given in Table 1. $a(\alpha)$ decreases with the solute content, this being mainly influenced by Zn, as its atomic radius is smaller than those of Al and Ag. A fraction of Zn retains solved in the SC alloys. The unit-cell parameters of the equilibrium phase, $\epsilon(\text{hcp})$, formed in the SC alloys are given in Table 2.^[23,24] These parameters decrease as the solute (Zn) content increases. The values of $a(\epsilon)$ and $c(\epsilon)$, extrapolated to 5 at% solute (i.e., to 0 at% Zn), are close to the unit-cell parameters of the γ -phase in Al-Ag alloys.^[2] For alloy 3, $a(\epsilon)$ is almost equal to the spacing $d_{\alpha110}$.

The WQ-aged alloys show, upon aging, the precipitation sequence GPZ (fcc) $\rightarrow \epsilon'(\text{hcp}) \rightarrow \epsilon(\text{hcp})$. GPZ and initial precipitates, ϵ' , are shown in Fig. 13.^[23] A line of zero contrast through the GPZ indicates strains in $\alpha(\text{M}/\text{GPZ})$ around GPZ. For alloys with $\text{Ag}/\text{Zn} > 1$, GPZ are spheres; for alloys with $\text{Ag}/\text{Zn} \leq 1$, GPZ are also cubes and ellipsoids. GPZ exhibit broad XRD lines; an example is shown in Fig. 14.^[23] Diffraction lines of GPZ become narrower with aging due to their growth, from 3 or 4 to 6 nm for alloys 1 and 2, and to 8–9 nm for alloys 3–5; these values followed from XRD line broadening and TEM. The misfit between $a(\text{GPZ})$ and $a[\alpha(\text{M}/\text{GPZ})]$ in the WQ-aged alloys changes from -0.4% for alloy 1 and to -2% for alloy 5 due to the increased Zn content in the zones. During aging, the misfit decreases due to a diffusion of Zn away from the zones.^[23,24] The metastable phase, ϵ' , is analogous to γ' in Al-Ag alloys. The orientation relationship between ϵ' and ϵ platelets and the α -phase is $\epsilon', \epsilon\{001\} \parallel \alpha\{111\}$; $\epsilon', \epsilon[110] \parallel \alpha[110]$.^[20,21]

Diffraction lines of $\alpha(\text{M}/\text{GPZ})$ split in two components on aging, the high-angle component corresponds to the WQ alloy, and the low-angle component to the SC alloy. The former component (containing mainly GPZ) transforms to the latter (having ϵ' precipitates) on aging. The separation between the components is small (amounting $\approx 0.3^\circ$ at $2\theta \approx 138^\circ$). This effect is interpreted as the discontinuous precipitation of ϵ' , similar to that observed in Al-Cu^[7] and Al-Zn^[4,12] alloys (where the separation increases with the Zn content).

Table 2 Unit-cell parameters of ϵ in the SC alloys and of ϵ' in the WQ-aged alloys, measured at RT

Alloy	$a(\epsilon)$ (in nm)	$c(\epsilon)$ (in nm)	$c(\epsilon)/a(\epsilon)$	$a(\epsilon')$ (in nm)	$c(\epsilon')$ (in nm)	$c(\epsilon')/a(\epsilon')$
1	0.2875(1)	0.4562(1)	1.587	0.2867(2)	0.4557(2)	1.589

Fig. 13 GPZ (small spots) and initial precipitates ϵ' (bigger spots) in the WQ Al-Ag-Zn alloy 4

Source: From Popović et al.^[23]

The unit-cell parameters of ϵ' are also given in Table 2. The WQ alloys 1 and 2 show rather sharp ϵ' diffraction lines 100, 002, and 101 after 2 days of aging. As aging proceeds, other ϵ' diffraction lines appear not changing their positions; it is found that $a(\epsilon) > a(\epsilon') > d_{\alpha110}$, $c(\epsilon) > c(\epsilon')$. For alloy 3, ϵ' diffraction lines 100 and 200 are rather sharp, but those with $l \neq 0$ consist of a sharp component and a broad one. This effect is attributed to ϵ' precipitates of two different sizes with similar unit-cell parameters. It is found that $c(\epsilon) > c(\epsilon')$; $a(\epsilon) \approx a(\epsilon') \approx d_{\alpha110}$, meaning a partial coherence between the phases $\alpha(M/\epsilon')$ and ϵ' . Diffraction lines of ϵ' in alloy 3 do not move as aging proceeds. Alloys 4 and 5 show rather sharp ϵ' diffraction lines at the initial aging. After a prolonged aging, ϵ' diffraction lines

consist of a sharp component and a broad one; this effect is more pronounced for alloy 5 (Fig. 15) than for alloy 4. For the broad component, $d_{\epsilon'100} \approx d_{\epsilon100}$; for the sharp one, $d_{\epsilon'100} \approx 3^{1/2} d_{\alpha110} / 2$. The sharp component moves to the broad one on aging; the latter does not move but sharpens. After a prolonged aging, $a(\epsilon) \approx a(\epsilon') < d_{\alpha110}$, $c(\epsilon) > c(\epsilon')$. The sharp component of ϵ' diffraction lines for alloys 3–5 corresponds to the discontinuously nucleated ϵ' , whereas the

Source: From Popović et al.^[23]

broad component results from a direct transition of GPZ into ϵ' . After aging at 620 K and slow cooling to RT, these alloys show only sharp diffraction lines of precipitates, close to those of ϵ .

***In Situ* XRD Study of Quenched-aged Alloys at High Temperature**

As mentioned previously, the microstructure of the WQ-aged alloys, being a two-phase system, $\alpha(M/\epsilon') + \epsilon'$, is different from that of the SC alloys. Crystal grains of $\alpha(M/\epsilon')$ are strained around the ϵ' platelets that have variable sizes. Diffraction patterns of the alloys that were stored at RT for 38 years remain rather unchanged, except for small sharpening of diffraction lines. These alloys were studied *in situ* by XRD at high temperature during heating from RT to a temperature, T_i , higher than the solid solution temperature, T_{ss} , and then during cooling back to RT. Parts of XRD patterns of the alloy 5 at selected temperatures are shown in Fig. 16, during the heating run. Similar diffraction patterns were observed for other studied alloys. As the temperature of the WQ-aged/stored alloys increases above RT, a slight sharpening of diffraction lines of both $\alpha(M/\epsilon')$ and ϵ' is observed due to strain annealing. At the same time, a gradual shift of diffraction lines takes place due to thermal expansion. The coefficient of thermal expansion of ϵ' is slightly smaller along the a -axis, $\alpha(a) = 2.3(3) \times 10^{-5} \text{ K}^{-1}$, than along the c -axis, $\alpha(c) = 2.6(3) \times 10^{-5} \text{ K}^{-1}$, measured in the interval from RT

to 500 K. Thermal expansion of $\alpha(M/\epsilon')$ is similar to that of ϵ' along the a -axis. Above $\sim 500 \text{ K}$, a gradual dissolution of ϵ' in $\alpha(M/\epsilon')$ takes place, manifesting in an enhanced decrease of ϵ' diffraction intensities. At the same time, the shift of ϵ' diffraction lines toward smaller Bragg angles is accelerated. The solution of Zn, from the ϵ' precipitates, in $\alpha(M/\epsilon')$ compensates or even reverses the shift of its diffraction lines due to thermal expansion. The solid solution temperature, T_{ss} , is estimated from the extrapolation of ϵ' diffraction intensities to zero. T_{ss} depends on the alloy composition, amounting $\sim 720, 700$, and 680 K for alloys 3, 4, and 5, respectively. The dissolution of ϵ' is followed by crystal grain coarsening of $\alpha(M/\epsilon')$.^[23,24]

In the cooling run, the alloys exhibit a temperature hysteresis in reversal changes. The precipitation of ϵ' starts at a temperature lower for 10–20 K than that at which precipitates dissolve on heating. The precipitation of ϵ' on cooling causes fragmentation of $\alpha(M/\epsilon')$ grains. The dependence of the unit-cell parameters of ϵ' on the temperature during cooling is little different from that during heating. After a completion of the heating and cooling cycles, the unit-cell parameters of the ϵ' precipitates are very close to those of the equilibrium phase, ϵ . The phase $\alpha(M/\epsilon')$ approaches $\alpha(M/\epsilon)$ and its diffraction lines are slightly shifted toward smaller Bragg angles, compared to their position before heating; this may mean a smaller fraction of Zn retained solved in $\alpha(M/\epsilon')$. Diffraction lines of precipitates formed in alloys 3–5, after a completion of the heating and cooling cycles, do not show composite profiles anymore.^[23,24]

Al-Zn-Mg ALLOYS

A number of papers have been devoted to the study of decomposition processes, structure, and properties of Al-rich Zn-Mg alloys, with respect to the composition and applied heat treatment, by TEM, SAXS, hardness tests, and so on (e.g., references cited in the work of Popović

et al.^[25]). In this review, the main results of the study of microstructure of a series of Al-4.5 at% Zn- x at% Mg alloys by XRD are described, with $x = 0, 0.05, 0.50, 1.00, 1.50, 2.25$, and 3.00 .^[25] The alloys were held at $T_i = 775$ K for 2 h and then quenched in water at RT (WQ specimens). Also, the alloys were held at $T = 525$ K for 5 days and then slowly cooled to RT over 15 days (SC specimens).

Parts of Debye-Scherrer diffraction patterns of pure and annealed Al and WQ alloys with 0.05 and 3.00 at% Mg, taken at RT within 3 h after quenching, are shown in Fig. 17. These patterns contain high Bragg-angle diffraction lines 511 + 333 and 422 (resolved into the spectral doublet $K\alpha_1$ and $K\alpha_2$).^[25] All the WQ alloys contain GPZ; their size decreases, from ~ 3 to ~ 1 nm, as at% Mg increases (Table 1 in the work of Popović et al.^[25]). Parts of the counter diffractometer patterns, taken at RT within 30 min after quenching, containing low Bragg-angle diffraction lines of the SC alloys with 0.05, 2.25, and 3.00 at% Mg, are shown in Fig. 18. The SC alloys with 0 and 0.05 at% Mg contain $\beta(\text{Zn})$, whereas those with 0.5–2.25 at% Mg contain η precipitates (MgZn_2 , $P6_3/mmc$, $a = 0.5223$, $c = 0.8569$ nm, $c/a = 1.64$ at RT^[26]). The SC alloy with 3.00 at% Mg is a three-phase system: $\alpha(\text{M}/\eta, \text{T}) + \eta(\text{MgZn}_2) + \text{T}$ (approx. composition $\text{Al}_2\text{Mg}_3\text{Zn}_3$, $Im\bar{3}$, a varying from 1.429 to 1.471 nm at RT depending on the Zn content; references in the work of Popović et al.^[25]). The unit-cell parameters of $\alpha(\text{M}/\text{P})$ for the WQ and SC alloys as a function of at% Mg are shown in Fig. 19, where P denotes the occurring precipitates: GPZ in the WQ alloys; $\beta(\text{Zn})$, $\eta(\text{MgZn}_2)$, or $\text{T}(\text{Al}_2\text{Mg}_3\text{Zn}_3)$ in the SC alloys.^[25]

$a[\alpha(\text{M}/\text{GPZ})]$ increases almost linearly with at% Mg. It is supposed that the whole content of Mg is solved in $\alpha(\text{M}/\text{GPZ})$, in line with statements in literature: the solubility of Mg in Al is twice as big as that of Zn in Al; the mobility of the Mg-vacancy pair is smaller than that of the Zn-vacancy pair; the atomic radius of Mg (0.160 nm) is bigger than that of Zn. In case the whole content of Mg were solved in $\alpha(\text{M}/\text{GPZ})$, the calculated $a[\alpha(\text{M}/\text{GPZ})]$ would be 0.40609 nm for the alloy with 3.00 at% Mg. The measured value at RT, 0.40610(3) nm, is in agreement with the calculated one.^[25]

The unit-cell parameter of the Mg-free SC alloy, $a[\alpha(\text{M}/\beta)]$, amounts to 0.40448(3) nm at RT, being in agreement with the average value found for the SC Al-Zn alloys, 0.40445(10) nm (cited above), which is independent of $x(\text{Zn})$. The SC alloy with 0.05 at% Mg has a little bigger $a[\alpha(\text{M}/\beta)]$ due to Mg solved in $\alpha(\text{M}/\beta)$. For the SC alloys with 0.50–2.25 at% Mg, $a[\alpha(\text{M}/\eta)]$ slowly increases due to a decreasing fraction of Zn solved in $\alpha(\text{M}/\eta)$. The remaining Zn is used to form $\eta(\text{MgZn}_2)$. The value of $a[\alpha(\text{M}/\eta, \text{T})]$ for the alloy with 3.00 at% Mg also corresponds to that continuous increase. The measured unit-cell parameter of the T-phase at RT is 1.403(1) nm.^[25]

The SC alloys with 1.50 and 2.25 at% Mg have been studied *in situ* by XRD during slow heating from RT to $T_i = 675$ K and slow cooling back to RT. Parts of the counter diffractometer patterns of the alloy with 1.50 at% Mg, taken

at RT, 650 and 675 K, are shown in Fig. 20.^[25] Diffraction lines of $\eta(MgZn_2)$ have small intensities and appear only at low Bragg angles. As the temperature increases, diffraction lines of both $\alpha(M/\eta)$ and $\eta(MgZn_2)$ move toward smaller Bragg angles due to thermal expansion. Thermal expansion of $\eta(MgZn_2)$ is similar for both studied alloys, being anisotropic: $\alpha[110] = 5.1(5) \times 10^{-5} \text{ K}^{-1}$; $\alpha[001] = 3.1(3) \times 10^{-5} \text{ K}^{-1}$. The intensities of diffraction lines of both $\alpha(M/\eta)$ and $\eta(MgZn_2)$ decrease as the temperature increases, due to increased thermal vibrations of atoms. Above ~ 525 K, the diminution of intensities of diffraction lines of $\eta(MgZn_2)$ is enhanced due to dissolution of $\eta(MgZn_2)$ in $\alpha(M/\eta)$. At 665 K, no traces of diffraction lines of $\eta(MgZn_2)$ are observed (Fig. 20). By extrapolation of the dependence of diffraction line intensities of $\eta(MgZn_2)$ on temperature (above 575 K) to zero, T_{ss} is found to be $\sim 665(5)$ K for both studied alloys. During cooling to RT, precipitation of $\eta(MgZn_2)$ takes place and intensities of its diffraction lines gradually increase.^[25]

Microstructure of Aluminum Alloys: Effect of Hardening Conditions

Hülya Demirören

Faculty of Technology, University of Firat, Elazığ, Turkey

Abstract

In the present article, aluminum and its heat treatments were expressed. Also it was investigated that the influence of quenching type after solutionizing heat treatment of cast Al-8.88Si-3.38 Cu on the microstructure has been reported. Alloys were prepared by controlled melting and casting. All the alloys were solutionized at 525°C for 4 h followed by water quenching at 65°C for 1, 15, 30, 60, and 90 min, respectively, and aged at 175°C for 4 h. Then they were cooled at room temperature. It was performed SEM–EDX analysis and X-ray analysis. From the analysis, it was determined Al₂Cu and Al₇FeCu₂ phases. It was determined that those phases reinforce the microstructure. As a result, the type of quenching after solution treatment is very important for aluminum alloys.

Keywords: Aluminum alloys; Hardness; Quenching; Solution heat treatment.

ALUMINUM ALLOYS AND HEAT TREATMENTS

Aluminum alloys encompass a wide range of chemical compositions and product forms that can be manufactured by all available metalworking techniques and standard casting process (ASM). Aluminum castings find extensive applications in industries because of the advantages. They offer such advantages as good casting characteristics, corrosion resistance, and high strength to weight ratio.^[1] Because of that, they are widely used in responsible structures, due to their optimum combination of physical and mechanical properties.^[2] Especially, the usage of aluminum–silicon casting alloys for automotive, electrical, aerospace industries and food packing has increased steadily in the recent years. Low strength is the major limitation of application for these materials. Strengthening of aluminum and its alloys by using severe plastic deformation techniques can expand their usage in the industry.

Heat treatment is an operation involving heating at a specific rate, soaking at a temperature for a certain period of time, and cooling at some specified rate to obtain desired microstructure, good mechanical, physical, and magnetic properties and metallurgical structure. Heat treating means that it is restricted to specific operations operated to increase strength and hardness of the precipitation-hardenable wrought and cast alloys. These are named as “heat-treatable” alloys to distinguish them from those alloys. In these alloys, it is not important that strengthening be obtained from heating and cooling.

Typical automotive parts include cylinder head, piston, wheels, intake manifold, etc. Automotive components

often require complex-shaped designs with high strength. At present, the required material properties are achieved by thermally treating the material. Generally, this thermal treatment consists of three main processes: First, solution heat treatment (SHT): this is where the material is held at an elevated temperature for a sufficient amount of time. Solution treatment at a relatively high temperature is performed to dissolve Cu particles formed during solidification to achieve a high and homogeneous concentration of the alloying elements in solid solution. Second, quenching: this is when the material is rapidly cooled from the SHT temperature to room temperature to obtain a super-saturated solid solution (SSSS) of solute atoms and vacancies. Finally, aging: age hardening is the final stage in the development of the properties of heat-treatable alloys. Age hardening is a process that causes precipitation from the SSSS, either at room temperature (natural aging) or at an elevated temperature (artificial aging). Microstructural changes occur during these three stages.

The selection of heat treatment processing technique for a given constitutional formulation depends on the level of microstructurally properties and industrial adaptability and reproducibility in terms of microstructure, and physical, mechanical, and electrical properties.^[1]

The commercial heat-treatable aluminum alloys are based on ternary or sometimes quaternary systems (Fig. 1) with respect to the solutes involved in developing strength and hardness can be increased by heat treatment include 2xxx, 6xxx, and 7xxx series wrought alloys and 2xx.0, 3xx.0, and 7xx.0 series casting alloys (ASM heat treating of aluminum). 2xxx alloys contain copper as the principal

Fig. 1 Main alloying elements of aluminum alloys

alloying element, whereas other alloys notably contain magnesium. 6xxx alloys contain magnesium and silicon as the principal alloying element. 7xxx alloys are alloys in which zinc is the principal alloying element, but other elements such as magnesium, chromium, copper, and zirconium may be added. They can be strengthened by heating and then quenching or rapid cooling. Recent research has focused on the 6xxx series alloys. Production of aluminum is illustrated in Fig. 2, schematically.

Aluminum alloys are produced by three methods:

First, natural aging should be mentioned. Most alloys exhibit property changes at room temperature after quenching. This is called “natural aging.” The strongest aluminum alloys (2xxx, 6xxx, and 7xxx) are produced by age hardening. The solid solution retained at the instant of quenching is unstable at room temperature and hardening phases immediately begin to precipitate. This process is termed natural aging. The more highly alloyed members of the 6xxx wrought series, the copper-containing alloys of the 7xxx group, and all of the 2xxx alloys are almost always solution heat treated and quenched. For some of these

alloys—particularly the 2xxx alloys—the precipitation hardening that results from natural aging alone produces useful tempers (T3 and T4 types) that are characterized by high ratios of tensile to yield strength and high fracture toughness and resistance to fatigue. For the alloys that are used in these tempers, the relatively high supersaturation of atoms and vacancies retained by rapid quenching causes rapid formation of Guinier–Preston (GP) zones, and strength increases rapidly, attaining nearly maximum stable values in 4 of 5 days. Tensile property specifications for products in T3- and T4-type tempers are based on a nominal natural aging time of 4 days. In alloys for which T3- or T4-type tempers are standard, the changes that occur on further natural aging are of relatively minor magnitude, and products of these combinations of alloy and temper are regarded as essentially stable after about 1 week.

In contrast to the relatively stable condition reached in few days by 2xxx alloys that are used in T3- or T4-type tempers, the 6xxx alloys and, to an even greater degree, the 7xxx alloys are considerably less stable at room temperature and continue to exhibit significant changes in mechanical properties for many years. Because of the relative instability of the 7xxx alloys, the naturally aged temper (after SHT and quenching) is designated by the suffix letter. For a specific description of this condition, the time of natural aging should be included.

Aging characteristics vary from alloy to alloy with respect to both time to initial change in mechanical properties and rate of change, but aging effects always are less-ended by reductions in aging temperature. With some alloys, aging can be suppressed or delayed for several days by holding at a temperature of -18°C or lower. It is usual practice to complete forming and straightening before aging changes mechanical properties appreciably. When scheduling makes this impractical, aging may be avoided in some alloys by refrigerating prior to forming.

Fig. 2 Semi-schematic processing schedule for high-strength Al alloys^[3]

It is a conventional practice to refrigerate alloy 2024-T4 rivets to maintain good driving characteristic. Full-size wing plates for current-generation jet aircraft have been solution heat treated and quenched at the primary fabricating mill, packing in dry ice in specially designed insulated shipping containers and transported by rail about 200 miles to the aircraft manufacturer's plant for forming.

Unanticipated difficulties may arise as a result of failure to control refrigerator or part temperature closely enough. If opening of the cold box to insert or remove part is done too frequently, the cooling capacity of the refrigerator may be exceeded. At times, the rate at which heavy-gage parts can be cooled in a still-air cold box has been found to be insufficient. This problem has been solved in one plant by immersing parts in a solvent at -40°C before placing them in the refrigerator.^[4]

In general, the principles and procedures for heat treating wrought and cast alloys are similar. The major differences between solution-treating conditions for casting and those for wrought products are found in soak times and quenching media. Solution of the relatively large microconstituents present in casting requires longer soaking periods than those used for wrought products. When heat treatment of casting must be repeated, solution times become similar to those for wrought products, because the gross solution and homogenization has been accomplished and is reversible under normal conditions. Reduction of stresses and distortion from quenching are also important, because castings generally are complex shapes with variations in section thickness.

Different casting process and foundry practices also result in microstructural differences with relevance to heat treatment practice, because the coarser microstructures associated with slow solidification rates require a longer SHT exposure. Therefore, the time required at temperature to achieve solution is progressively shorter for investment, sand, and permanent mold castings. Foundry practice (chills, gating, and type of mold) also plays an important role in the response of a casting to heat treatment. For example, thin-wall sand casting produced with extensive use of chills can often display finer microstructures than heavy-section permanent mold parts produced in such a way that process advantages are not exploited.

For these reasons, SHT practices can be optimized for any specific part to achieve solution with the shortest reasonable cycle once a production practice is finalized, even though most foundries and heat treaters will standardize a practice with a large margin of safety. There also exists a fundamental difference between unmodified and modified alloys in which the size and shape of silicon crystals are modified with addition of elements such as calcium, sodium, strontium, or antimony. Modified alloys undergo rapid spheroidization that is not achieved in unmodified alloys even after very long times. The practical implication is that shorter SHT could be employed in fully modified castings. The micro-segregation of silicon and magnesium is not severe in the aluminum–silicon–magnesium casting

alloys, and hence it takes only a short time to homogenize the alloy and to place Mg_2Si into solution.

In some alloys, notably those of the 2xxx series, cold working of freshly quenched material greatly increases its response to later precipitation heat treatment. Mills take advantage of this phenomenon by applying a controlled amount of rolling (sheet and plate) or stretching (extrusion, bar, and plate) to produce higher mechanical properties. However, if the higher mechanical properties are used in design, reheat treatment must be avoided.

In some alloys, sufficient precipitation occurs in a few days at room temperature to yield stable products with properties that are adequate for many applications. These alloys sometimes are precipitation heat treated to provide increased strength and hardness in wrought or cast products. Other alloys with slow precipitation reactions at room temperature are always precipitation heat treated before being used.

The rate of precipitation from the SSSS existing immediately after quenching increases as the temperature of the metal is raised above room temperature. Precipitation occurs naturally at room temperature, providing useful degrees of precipitation hardening for some alloys. Effective control of degree of precipitation and the various final characteristics is accomplished by prescribed practices for time and temperature. Within limits, approximately equivalent effects can be obtained by shorter periods of time at higher temperatures or longer times at lower temperatures. Most wrought aluminum alloys are strengthened by age hardening. The work hardening of aluminum alloys is important for the formability of aluminum sheets and profiles and the plastic collapse of aluminum structures.^[5] Solute elements, hardening precipitates, and dispersoids contribute to the yield strength of aluminum alloys, since they act as distributed pinning points for mobile dislocations, thus increasing the shear stress required to move the dislocations. Solute elements also contribute to an increased work hardening by reducing the dynamic recovery rate^[6] (Fig. 3).

Generally, this thermal treatment consists of three main processes:

1. **Solution treatment**, or solutionizing, is the first step in the precipitation hardening process where the alloy is heated above the solvus temperature and soaked there until a homogeneous solid solution (α) is produced. The θ precipitates are dissolved in this step and any segregation present in the original alloy is reduced. The most complete degree of solution that can be practically and economically achieved is desirable for optimal properties. Different casting processes and foundry practices result in microstructural differences with relevance to heat treatment practice. Coarser microstructures associated with slow-solidification rate processes require longer exposure at SHT temperature for solution to be achieved. SHT practices may be optimized for any specific part to achieve

Fig. 3 Precipitation hardening method^[4]

solution with the shortest reasonable cycle once a production practice is finalized. Superior properties can be achieved with furnaces, thermocouples, and furnace controls that are capable of operating within close temperature ranges near the eutectic melting region, recognizing the resistance of cast structures to melting based on diffusion considerations.^[7]

2. **Quenching** is the second step where the solid α is rapidly cooled forming a SSSS of α_{ss} that contains excess copper and is not an equilibrium structure. The atoms do not have time to diffuse to potential nucleation sites and thus θ precipitates do not form. The objective of quenching is retention of the highest possible degree of solution with the lowest level of induced residual stresses and the least warpage or distortion consistent with commercial or specified requirements. Specific parameters may be associated with the heating of parts to achieve solution, and separate parameters apply to the steps required to achieve the highest postquench degree of retained solution. Rapid cooling from solution temperature to room temperature is critical, difficult, and often the least-controlled step in thermal processing. Water is the quench medium of choice for aluminum alloys, and its temperature has a major effect on results. Most commercial quenching is accomplished in water entered near the boiling point, but room temperature, 65°C, and 80°C are common standardized alternatives. Corrosion and stress corrosion performances are enhanced by rapid quenching, and quenchant temperature is the dominant factor.^[7]
3. **Aging** is the third step where the supersaturated α , α_{ss} , is heated below the solvus temperature to

produce a finely dispersed precipitate. Atoms diffuse only short distances at this aging temperature. Because the supersaturated α is not stable, the extra copper atoms diffuse to numerous nucleation sites and precipitates grow. The formation of a finely dispersed precipitate in the alloy is the objective of the precipitation hardening process. The fine precipitates in the alloy impede dislocation movement by forcing the dislocations to either cut through the precipitated particles or go around them. By restricting dislocation movement during deformation, the alloy is strengthened.

Natural or artificial precipitation hardening following SHT and quench most powerfully differentiates the properties of cast aluminum products. Hardening is defined as changes in metallurgical structure resulting in increased resistance to deformation. The process of hardening is accelerated by artificially aging at temperatures ranging from approximately 90°C to 260°C. In natural and artificial aging, supersaturation, which characterizes the room temperature solution condition, is relieved by the precipitation of solute that proceeds in stages with specific structural effects.^[7]

Mechanism of precipitation hardening is as follows:

- Formation of very small particles of second, or precipitate, phase.
- During precipitation hardening, lattice strains are established at the precipitate–matrix interface.
- There is an increased resistance to dislocation motion by these lattice strains in the vicinity of the microscopically small precipitate particle.

The interaction matrix in principle defines both the flow stress and the hardening rate. The flow stress is the stress that is necessary to overcome the dislocation interaction forces and start the dislocation movement and plastic deformation. The work hardening, on the other hand, is caused by the accumulation of immobile dislocations. Stronger dislocation interactions between some slip systems will lead to a decrease in the mean free path of the dislocations on these slip systems and as a result to an increase in the work hardening. The details of these mechanisms and whether the flow stress and the dislocation density evolution are controlled by the same interaction matrix are still not well known.^[8]

The precipitation processes from which this hardening is derived are well known to be sensitive to the presence of selected trace elements addition or microalloying, which can change the process and/or kinetics of precipitation in many age-hardenable alloys. Precipitation in commercial aluminum alloys usually starts from the formation of GP zones, which may be regarded as fully coherent metastable precipitates. Subsequent evolution of the microstructure involves the replacement of the GP zones with more stable phases. This occurs primarily because GP zones are isomorphous with the matrix and, therefore, have a lower interfacial energy than intermediate or equilibrium precipitate phases that possess a distinct crystal structure. As a result, the nucleation barrier for GP zones is significantly smaller. The typical size of GP zones is in the order of tens of nanometers, and the chemical composition of these precipitates is not easily measured, even with a state-of-the-art analytical electron microscope. Furthermore, many experimental results suggest that solute clustering occurs prior to precipitation of GP zones, and this modifies both the nature and kinetics of precipitation of GP process. Although GP zones are readily observed by modern TEM, clear observation of solute clusters is not possible, even with a high-resolution transmission electron microscope. The atom probe can detect single atoms, and thus, it is possible to clearly detect the clustering of solute, which appears to be the earliest stage of age hardening. Thus, the use of the atom probe technique for studies on precipitation processes can shed light on many of the remaining problems in the physical metallurgy of age-hardenable aluminum alloys. This is also of current technological interest, given that variation in the heat treatment, strain conditions prior to aging, and alloy composition induce significant changes in microstructure, and there remains a considerable potential for the design of high-strength aluminum alloys. Recent technological impetus for exploring the alloy design and development has mainly come from the aerospace and automobile industries.

The most widely studied age hardening alloy system is Al–Cu and several commercial alloys. Although the alloy is composed of only two elements, the microstructural evolution is complex and the precipitation sequence varies depending on the degree of supersaturation and the

aging temperature. Figure 2 shows the Al-rich corner of the equilibrium Al–Cu phase diagram and includes the metastable solvus boundaries for GP zones, θ'' and θ' . Over many studies, it has been proposed that the decomposition sequence in this system contains one or more of the following processes:

The complete precipitation sequence can only occur when the alloy is aged at temperatures below the GP zone solvus (Fig. 4). Various steps in the process may be suppressed by aging at temperatures close to or above the intermediate solvus temperatures.

Age hardening–strengthening has three main mechanisms;

- Coherency strain hardening results from the interaction between dislocations and the strain fields surrounding GP zones and/or coherent precipitates.
- Chemical hardening results from the increase in applied stress required for a dislocation to cut through a coherent (or semi-coherent) precipitate.
- Dispersion hardening occurs in alloys containing incoherent precipitates or particles—i.e., typically those that have been overaged. This hardening results from the increased shear stress required for dislocations to bypass these obstacles.

Maximum hardness and strength occur when the amount of GP zone is essentially at a maximum, although some contribution may also be provided by θ' . As amount of θ' increases, particle growth eventually decreases the coherency strains. This loss in coherency, together with the simultaneous decrease in GP, causes overaging. When the noncoherent θ appears, the alloy is softened far beyond the maximum strength condition.

To understand the mechanism of the increase in hardness that accompanies aging, it is useful to examine the

Fig. 4 Al-rich corner of the equilibrium Al–Cu phase diagram

individual stages of the microstructural evolution described above. By the early 1960s, X-ray diffraction and resistivity measurements suggested that solute atoms may spontaneously cluster in certain Al alloys after quenching to temperatures below the metastable GP zone solvus line. The formation of these clusters precedes the formation of GP zones.^[4]

Further aging results in a second rise in hardness attributed to θ'' precipitation. The formation of θ'' is also followed by a shorter incubation period and the subsequent formation of the metastable θ' phase. Prolonged aging results in the formation of the equilibrium θ phase. Each precipitation stage does not necessarily correspond to the stages observed in the hardness curve, and more than two phases can coexist at a given stage of the transformation sequence from one phase to another usually involves heterogeneous nucleation at the sites of earlier products, resulting in fine and uniform precipitate dispersions.

In Al–Cu alloys, the hardening observed at room temperature is attributed to localized concentrations of copper atoms forming in GP zones. These consist of two-dimensional copper-rich regions of disklike shape. At temperature of 100°C and higher, the GP zones disappear. Although only a few atom layers in thickness, it is considered to be three-dimensional and to have ordered atomic arrangement. Those described above were isotropic hardening. In addition, it is mentioned kinematic hardening.

Kinematic hardening: Numerous papers have been written describing kinematic hardening of single phase, multiphase, and discontinuously reinforced metals and alloys. The microstructural genesis of the observed kinematic hardening behavior has most often been explained in terms of micro-mechanical concepts. Kinematic hardening is explained by Bauschinger effect and determined Bauschinger effect test.^[9] Bauschinger effect and similar responses can use the kinematic hardening rule. A hardening during tension will lead to a softening in a subsequent compression due to these effects. Wierzbńska and Sienawski's studies performed on the two casting aluminum alloys AlCu₄Ni₂Mg and AlCu₆Ni. The alloys were exposed to heat treatment T6 and then annealing at 523 and 573 K for 150 and 500 h. In metallographic investigation, they observed large, irregular-shaped precipitates of intermetallic phases, located on the dendrite boundaries of solid solution α -Al, and dispersive-, spheroidal-, and strip-shaped hardening phase precipitates homogeneously distributed throughout the solid solution were observed. Examination of the alloys' microstructure after prolonged annealing revealed that the precipitates of Al₆Fe and S-Al₂CuMg phases and large precipitates of intermetallic phases at the dendrite boundaries practically did not change even after

very long time of annealing. Whereas, significant increase in size of dispersive particles of θ' -Al₂Cu hardening phase was observed. They determined that AlCu₄Ni₂Mg and AlCu₆Ni growth of the hardening phase precipitates occurred as a result of long-term thermal loading, which was proportional to the temperature and time of annealing. However, higher coarsening propensity was found for the Al₆CuNi alloy, which arose from higher content of the element forming hardening phase (6% Cu). It was confirmed by analysis of the change of shape and size of the θ' -Al₂Cu precipitates in both alloys after annealing at 573 K for 150 and 750 h. As a result, the alloy consists largely in coarsening and the change of the shape of hardening phase particles (θ' -Al₂Cu). The alloys studied are characterized by different content of Cu—primary element forming hardening phase.^[10]

In other study, Hurtalová et al. investigated hypoeutectic Al–Si alloy.^[11] They treated the alloys with age hardening. Age hardening consists of solution treatment at 515°C with holding time 4 h, water quenching at 40°C, and artificial aging by different temperatures of 150°C, 170°C, and 190°C with different holding times of 2, 4, 8, 16, and 32 h. As mechanical properties are principally controlled by the cast structure, structural parameters in alloys are very important. They observed the morphology changes of eutectic silicon after hardening, and eutectic silicon plates were spheroidized. They determined that Si particles decrease with increasing artificial aging. After age hardening, they studied Fe-rich intermetallic phases.^[12] They asserted that intermetallic phases act like stress raisers.

Monteiro et al. studied Al 6063 alloy has a good potential of hardening by precipitation as it includes intermetallic compound like Mg₂Si. This hardening occurs via solution treatment and then artificial aging. They performed thermal treatments at 423, 523, 623, and 723 K with times of 60, 600, 1800, 3600, 5400, and 7200 s for each temperature. They determined that similar structures occur, predominantly Mg₂Si and some β -Al₅FeSi in this alloys at 423 and 523 K. Crystalline defects decreased with increasing treatment time. They observed subgrains with size of 0.1 μ m dimension. They supposed that nucleation sites, which will be transformed into grains, are initially small and will have its grain size increased over time.^[13]

In the present article, the Al–Si–Cu alloy was used. The chemical composition is given in Table 1. The alloy was melted in an induction furnace and then casted. The samples were cut in dimensions 10×8×8 mm. All alloys were solution treated at 525°C for 4 h. They were exposed at 65°C to water for 1, 15, 30, 60 and 90 min and then cooled at room temperature and referred to as S1, S2, S3, S4, and S5, respectively. The heat treatment-free sample was

Table 1 The chemical composition of alloy (ETIAL160)

Alloy	Al	Si	Cu	Fe	Mn	Mg	Zn	Ti
E160	Balance	8.26	3.39	0.57	0.01	0.01	0.02	0.009

referred to as S6. Aging treatment was performed at 175°C for 4 h. The samples were mechanically polished with 1200 grit SiC paper. Etching was accomplished using Keller's reagent [0.5 HF–1.5 HCl–2.5 HNO₃–95.5 H₂O]. Optic photographs were obtained from Olympus microscope. SEM observations were made on a LEO-EVO 40 model scanning electron microscope at 20 kV. Energy-dispersive X-ray (EDX) analyses were performed using Quantax Microanalysis System having Bruker 125 eV detector. Hardness measurements were carried out using a Brinell hardness tester with a 2.5-mm diameter ball and a 31.2-kg applied load.

With studies in a light microscope, a typical undeformed structure is observed in cast specimens (Fig. 5) consisting of an aluminum matrix, Al–Si and Al–Cu eutectics, and also iron phases enriched with copper phase Al₂Cu may be present in the form of compact faceted particles or as a eutectic component, which is indicated by energy dispersion analysis data (1).

In photographs of alloy microstructure after treatment for solid solution at 525°C, 4 h, and exposure at 65°C for 1–90 min, there are Al–Si and Al–Cu eutectics, and also phases Al₂Cu and Al₇FeCu₂. Analysis of structure by scanning electron microscopy also shows that the phase enriched with copper has three main morphologies: compact, eutectic, and dispersed eutectic (Fig. 5). The concentration of aluminum and copper in Al₂Cu particles remains constant during dissolution, and copper is transferred into the matrix from their outer layer. Dissolution of Al₂Cu phase continues for several hours due to the slow diffusion rate of copper in aluminum and low treatment temperature, at which it is possible to carry out dissolution (Fig. 6).

As seen in Figs. 7 and 8, the second phases are present intensely in comparison to the others, in unheat-treated

sample. There are more peaks in sample with heat treated and waited at 65°C. It may be arising from the following: While it waits at 65°C, the second phases found time to form.

In Fig. 9, it is seen Al–Si eutectic and Al–Cu eutectic, and phases such as Al₂Cu and Al₇FeCu₂ are formed by Cu, Si, and Fe with Al. It is observed that Al₂Cu phase can be present in different types as blocky, eutectic, or as a mixture of both types.

The optic observations are shown in Fig. 9a. The main eutectic reaction occurred at ~535°C. The optic microscope morphology of complex eutectic phase was similar to that of the eutectic Al₂Cu phase. This phase is formed during solidification (Fig. 9b). It is referred as Cu-rich segregated phase. As seen in Fig. 9, more homogen microstructure and spherical second phases were obtained.

SEM observation confirms the earlier assertion that Cu-enriched phases appeared in three main morphologies: blocky, eutectic type, and fine eutectic type, as seen from Fig. 10. The concentration of Al and Cu in the Al₂Cu particles is constant during the dissolution process and Cu diffuses from the outer layer of the Al₂Cu particles into the matrix. Dissolution of Al₂Cu phases takes several hours due to the low diffusion rate of Cu in Al and the low solution treatment temperature allowed, as showed by Samuel et al.^[14]

Hardness values of heat-treated alloys depend mainly on the morphologies of eutectic Si, second phases, and precipitations.^[15] In order to improve the mechanical properties of Al–Si alloys, it is necessarily to make reinforcements in composition by adding alloying elements such as Cu, Mg, and Fe. Common precipitation hardening phases such as Al₂Cu, Al₇Fe₃Si_{0.3}, and Al₇FeCu₂ are formed by Cu, Mg, and Fe with Al.^[13,16,17]

Fig. 10 SEM observations of (a) unheat-treated and (b) heat-treated alloys

Fig. 11 Microhardness values of (a) matrix and (b) second phases^[1]

Figure 11 shows the values of microhardness of samples. The effects of time and temperature for hardening on the Brinell hardness are demonstrated. Microhardness increases when waiting period increases from 1 to 90 min. Microhardness values at 60 and 90 min are approximately the same. There are two important factors that can contribute to the microhardness increase for the alloys: (1) a higher content of nano-sized second phases and (2) homogen microstructure. It is apparent that extent of hardening required to produce maximum hardness or strength at a specific temperature.

Finally, with adequate time at temperature, the soluble constituents become spheroidized and may dissolve completely. Even relatively insoluble constituents become less angular, as corners of high energy dissolve. Hardening treatment reduces the coring inherent in cast structures, as composition gradients are reduced by diffusion. Hardening treatment also improves both strength and ductility by dissolving inherently brittle, intermetallic compounds, thus making the structure more homogeneous. The combination

of SHT and precipitation treatment is employed widely to obtain optimum microstructure. Homogeneous structure produced by SHT permits maximum response to a precipitation treatment.

MIG Welding of Aluminum Alloys

K. Yasuda

Abstract

MIG welding is used as a highly efficient process for various types of metal. It involves creating an arc between an electrode, wire and the metal to be welded (parent metal) under the gaseous shield of an inert gas such as argon, thereby causing the wire to melt and transfer to the parent metal. This paper mainly describes MIG welding in relation to aluminium alloys.

Keywords: Inverter pulsed MIG; Metal inert gas (MIG); Pulse arcs; Spatter.

INTRODUCTION

MIG welding is used as a highly efficient process for various types of metal. It involves creating an arc between an electrode wire and the metal to be welded (parent metal) under the gaseous shield of an inert gas such as argon, thereby causing the wire to melt and transfer to the parent metal. This paper mainly describes MIG welding in relation to aluminium alloys.

WELDING CONDITIONS AND THE TRANSFER OF MOLTEN METAL WIRE

The Basic Phenomenon

Due to the properties of carbon dioxide, an arc formed during carbon dioxide shielded welding concentrates at the lower end of the electrode wire. An effect of the arc concentration in this area is to push the molten metal upwards to form a large globule which then transfers to the parent metal, see Fig. 1. In contrast, when an inert gas such as argon is used as the shielding gas, the arc which forms is produced by the molten metal wire as a whole. When the weight of this molten mass exceeds what its surface tension can support, it detaches from the wire and transfers to the parent metal in a series of droplets. However, when the welding current is increased, the current density between wire and arc increases. This creates a ‘pinch’ effect on and a constriction is formed between the molten and solid parts of the wire thereby producing a stream of droplets, see Fig. 2. In MIG welding, a specific current (transition current) is found according to the type and diameter of the wire and type of shield gas, see Fig. 3. Above this current the molten metal transfers as a spray, and below as discrete droplets.¹

Transfer processes for molten metal wire in MIG welding are not only limited by current values; the relationship with the set voltage must also be considered.

Figure 4 shows the relationship between the transfer of molten metal and current and voltage. Transfer occurs as a spray above the transition current and also above a fixed voltage; below these, the molten metal and parent metal are liable to short-circuit during welding.² Short-circuit transfer occurs at voltages lower than this.

Pulse Arcs

As will be discussed below, pulsed MIG welding is used to broaden the applications of MIG welding. This method superimposes a commercial frequency pulse on to a base current which is below the transition current – the sum of the two currents exceeds the transition level. The moment the pulse current is applied, even at low intensity, not only does the molten metal transfer to the parent metal, but the stability of the arc is increased and overall performance is improved. Pulse level and filler wire characteristics determine the average base current and pulse current settings.

With previous thyristor-controlled pulsed MIG welding machines, the choice of pulse frequency was limited, but with the more recent inverter regulators capable of wave form control, not only is the range of frequency far wider but it is possible to carry out low frequency pulse welding similar to TIG welding (discussed below).

WELDING CONDITIONS AND SUITABLE APPLICATIONS

Welding under Conditions Suitable for Spray and Droplet Transfer

When standard MIG welding techniques (conventional MIG) were used, welding was carried out under conditions suitable for spray transfer which was characterised by small transferring particles of molten metal and a stable arc. As Fig. 4 indicates, when welding under spray transfer conditions, there is a need to create a relatively long arc

Fig. 1 Production of arc in carbon dioxide shielded welding

Fig. 2 Production of arc in MIG welding above transition current

Fig. 3 Effect of welding current on form of metal transfer in MIG welding

above the transition voltage. There is a tendency for the welds to have wide beads and for undercutting to occur when the filler wire is moved. As a result of this, it has recently become standard practice to lower the voltage and weld under short arc/droplet conditions.

Welding under either of these conditions needs to be carried out above a transition current and is usually used for welding horizontal corner sections and horizontal position medium and thick plates.

Fig. 4 Effect of current and voltage on metal transfer in MIG welding

Fig. 5 Results of lap welding of A5052P (t = 3 mm) by a fine MIG short arc

Welding under Short-Circuit Transfer Conditions

As a result of its characteristic short arc, in which the molten filler short-circuits with the parent metal, carbon dioxide shielded welding has a wide range of applications. This is because the high temperature of the arc caused by a thermal reaction with the carbon dioxide acts to moderate the cooling effect of the short-circuiting with the parent metal.

As Fig. 4 indicates, a short arc is created when the fixed voltage is reduced when using MIG welding techniques. However, MIG welding of aluminium with a short arc can be problematic:

1. Welding is carried out under a shield of inert gas making it impossible to produce a reaction comparable to that obtained when using carbon dioxide.
2. Heat conduction of the materials is good, which means that the cooling from short-circuiting has an adverse effect.
3. Problems arise when the wire buckles and becomes twisted when short-circuiting with the parent metal. To counteract this, a special MIG welding device is often used. This is a type of gun with a spool attached which feeds 0.6–0.8mm diameter wire. This application can only work when welding plates thinner than 1mm. However, when a compound gas with 2–3% of added oxygen is used as the gaseous shield, it becomes possible to weld 2–3mm thick plates using the device, see Fig. 5. When 1.2mm thick wire is used in a

standard MIG welding machines it becomes possible to carry out single-sided welding due to convectional effects similar to those when sheet steel is welded using a short arc and carbon dioxide, see Fig. 6.

Welding under Pulse Transfer Conditions

For MIG welding under spray (fine droplet) and short-circuit transfer conditions, there are limits on the thickness of the metal plates and the position in which successful welding can take place. These limitations are largely eliminated by using pulse MIG arc welding. A stable arc is produced using this technique, ensuring the successful transfer of molten metal wire stabilised by the pulse frequency adapted to this operation.

The basic conditions set for pulse MIG welding are:

1. Reducing the base current below the transition current in such a way as not to jeopardise the stability of the arc.
2. Aiming for the base current to be twice the value of the transition current (when it is too low the transferring particles are big and the arc unstable, and when it is too high the transferring particles are small and arc spraying increases).
3. Aiming for conditions in which molten metal transfers under a stable arc as the pulse intervals are determined by their relationship to the pulse current (when the intervals are too close together the transferring particles are big and the arc unstable, and when they are too far apart, arc spraying increases).
4. Aiming for the voltage to be $\pm 1.5V$ of the transition voltage while ensuring a stable arc, and aiming for the voltage to fit the form of the pulse.

The operational scope for welding various kinds of materials is widened considerably when pulse MIG arc welding is used. Aluminium in particular produces successful results by ensuring a stable arc, enabling the use of a large diameter wire, and minimising the problem of twisted wire.

Fig. 6 Results of one-side welding of A5052P ($t = 3\text{ mm}$) by MIG short arc welding

Welding Conditions and Spatter

Carbon dioxide shielded welding of steel creates a number of problems when spatter deposits on the parent metal during welding:³

1. Product appearance deteriorates.
2. When spatter deposits on the parent metal, it cools very quickly which can lead to cracking.
3. Stress concentrations occur at the edges of the spatter deposits which can lead to fatigue failure.

Points 1 and 3 can arise even when welding aluminium using MIG techniques, and so it is important to find ways of reducing spatter and the problems of spatter deposits.

Transfer of Molten Metal Wire and Spatter

With spray, droplet and pulse welding which are all characterised by small particles of transferring metal and a stable arc, the size of spatter globules is only 1mm or less, and spatter deposits are minimal.

Under short arc welding conditions both the amount of spatter and spatter deposits increase, and a high current setting produces spatter particles of 2–3mm in size (it is harder for these large particles to deposit on the parent metal which makes them easier to remove). However, the application of a small sub-transition current produces only small spatter particles and virtually no spatter deposits.

Gun Operation and Spatter

In semi-automatic MIG welding, use of a gun, the angle at which it is held and the target at which the arc is directed, can have considerable effect. The nearer the gun is held at right angles, facilitating transfer of molten metal to the parent metal, the more the quantity of spatter decreases, but when the angle of the gun is increased, as it is in standard forward welding, the amount of spatter increases. The amount of spatter also depends on where the gun is aimed in relation to the arc. If the gun is aimed at the centre of the molten pool, spatter increases, but the reverse happens if the gun is aimed at the tip of the molten pool. The most effective way to keep spatter at a minimum is for the molten metal to be transferred when there is as thin a layer as possible of molten metal in the pool. This is verified by the fact that spatter increases when welding at minimum velocity which must be taken into account when carrying out MIG welding of aluminium.

Spatter and Power Sources used in Welding

In recent years, various welding machines have been developed capable of high-precision current waveform control. Transistor-controlled pulsed MIG welding devices are even being used in conventional MIG welding, and

Fig. 7 Results of welding by inverter pulsed MIG

inverter-controlled pulsed MIG welding machines have also been developed.

Spatter is kept to an absolute minimum when these devices are used as the current is controlled rapidly and with great precision. Use of an inverter-controlled power source makes it possible to carry out low frequency pulsed MIG welding in which the high-frequency controlled current acts as the base current. This type of power source also enables welding of similar quality to TIG welding to be carried out; in this spatter deposits are minimal, see Fig. 7.

Ways of Preventing Spatter

Methods of preventing spatter and spatter deposits in MIG welding of aluminium alloys have been discussed above. The most effective way is generally considered to be by

correct choice of welding conditions, and using transistor and inverter-controlled power sources when welding. Furthermore, care should be taken to ensure that an adequate molten pool of the base metal is obtained at the location where welding starts, and the gun is manipulated so that no molten metal is created in front of the arc.

CONCLUSION

This paper has described MIG welding of aluminium alloys. Various aspects of this have been considered, including spatter formation, but the text has centred on fundamental factors in the transfer of molten metal, and on welding conditions in relation to methods of operation.

Various high-performance welding machines have been developed in recent years, and a large increase in the number of applications is expected.

Molten Aluminum: Inductive Technique for Electrical Conductivity Measurements

Sayavur Bakhtiyarov

Mechanical Engineering, New Mexico Institute of Mining and Technology, Socorro,
United States

Ruel Overfelt

Mechanical Engineering, Auburn University, Auburn, AL, 36801, United States

Abstract

A rotational, contactless inductive measurement technique has been used to determine the effect of pores and metallic insertions on the electrical resistivity of A2011 aluminum alloy at different temperatures. It is shown that the electrical resistivity increases with the total volume of pores and is also dependent on the pores locations and orientation. Additional energy losses were found on the contact surfaces between sample and insertions.

Keywords: Aluminum alloy; Electrical resistivity; Porosity; Thermal conductivity.

INTRODUCTION

Information on the electrical resistivity of molten alloys is especially important in many metallurgical processes such as electroslag remelting, electromagnetic stirring in continuous casting, and induction melting in foundries. The electrical resistivity of the metals and alloys in both solid and liquid phases is affected by the porosity formations and some immiscible inclusions. From a practical point of view, it is crucial to know the variation of the electrical resistivity with the pores and inclusions. However, there are no studies reported in this area.

Recently, Bakhtiyarov and Overfelt^[1,2] developed a rotational, contactless, inductive measurement technique to measure both the viscosity and the electrical conductivity of metals and alloys over wide ranges of temperatures. Preliminary tests conducted with low-melting point metals (lead and tin) and alloys (LMA-158 and Pb/Sn binary systems) showed a good agreement with data from the literature. This technique requires a reliable relationship between the electrical resistivity of the metal sample and the measured damping torque values. Braunbeck^[3] proposed the following relationship between the opposing mechanical torque (T) and the electric conductivity of a rotating liquid specimen (σ_e) in a DC external magnetic field of induction B :

$$T = \frac{\pi}{4} \sigma_e \omega L R^4 B^2 - \frac{\pi}{192} \frac{1}{\eta} \sigma_e^2 \omega L R^6 B^4, \quad (1)$$

where L and R are length and radius of the specimen, respectively; ω is the angular velocity of the rotating magnetic field; and η is the viscosity of the liquid specimen.

The magnetic induction and the radius of the specimen can be selected so that the second term in Equation (1) will become negligibly small compared with the first term for measurements on metals with unknown viscosity.^[4]

The objective of this paper is to study the effect of porosity formations and nonferrous inclusions on the electrical resistivity of A2011 aluminum alloy obtained by direct measurements using the rotational technique (with a cylindrical metal sample rotating in a two-pole DC magnetic field) over wide ranges of temperatures.

EXPERIMENTAL APPARATUS AND PROCEDURES

A schematic of the experimental apparatus to measure an electrical resistivity of metals and alloys over a wide range of temperatures is shown in Fig. 1. A computer-controlled Brookfield rheometer Model DV-III was used to provide a constant rotational speed to the metal sample and to measure the torque. This rheometer enables torque measurements from 0 to 673.7 dyne-cm at constant speeds from 0 to 250 RPM in 0.1 RPM increments. The rheometer has an RS232 serial port for communication with a local computer.

The temperature of the sample was characterized remotely by a portable two-color infrared thermometer M90 (Mikron®) focused into a hole in the bottom of the crucible assembly since thermocouple leads could not be inserted into the rotating samples. Focusing into the hole in the crucible bottom eliminated spurious temperature data from extraneous reflections into the infrared thermometer from the optical heaters. The infrared thermometer

Fig. 1 Experimental apparatus used for electrical resistivity measurements of solid and molten metals

output was calibrated to actual temperature by comparing against thermocouple data using a dummy load with 0.25% accuracy. The thermometer output was connected to the computer, and the temperature data obtained were synchronized with data for measured torque and angular velocity of the crucible.

Metal samples (19.05 mm diameter and 38.1 mm length) for testing were inserted into cylindrical high-purity alumina crucibles with a flat bottom. The extruded alumina crucibles (19.05 mm inner diameter and 152.4 mm length) were attached to the spindle of the rheometer through a specially designed coupler to provide concentricity to the rotating shaft, crucible and sample. The same sample diameter was maintained for each set of tests. The rotational technique of this geometry is exposed to the end effects in the crucible. This effect was eliminated from the results of two experiments accomplished with the different heights (25.4 and 38.1 mm) of the sample in the crucible at the same angular speed.

Two quartz infrared line heating elements (2 kW each) housed in elliptical cast aluminum frames were used to heat the samples in the experiments. The heated length of the chamber was 167 mm. The elliptical reflectors concentrated the infrared energy to the crucible surface (Fig. 2). Copper tube connections are provided for inlet and outlet flow of water to cool the lamp reflector bodies. Tap water at 15°C and 600 kPa was supplied to cool the unit.

The magnetic field was produced by two neodymium-iron permanent magnets. A Hall effect gaussmeter was

used to measure the magnetic field strength. The gaussmeter provides DC and AC field readings from $\pm 10^{-5}$ to ± 2 Tesla with 0.1% resolution. Changing the separation between the magnets allowed us to obtain magnetic fields of different magnitudes to be obtained. Contour mapping of the magnetic field strength revealed that the magnetic induction varies in both vertical and horizontal directions. It is estimated that the magnetic induction over the test sample varies $\pm 10\%$ in vertical direction and $\pm 7\%$ in horizontal direction compared to its average value. Neither the coupling system nor the alumina crucible had measurable effects upon the applied magnetic field.

RESULTS AND DISCUSSION

As a test sample we used A2011 aluminum alloy (Si-0.4%, Fe-0.7%, Cu-6%, and Zn-0.3%) popular in commercial applications. Two sets of experiments were conducted in this study. In the first set of the experiments, the cylindrical holes of 2.08 mm diameter were drilled through the samples in longitudinal or traversal directions to study the influence of the orientation of porosity formations on the electrical resistivity measurements. In the second set of the experiments, a longitudinal cylindrical hole of 4.00 mm diameter was drilled through the sample. The orientation and total holes volume are presented in Table 1. The experiments were conducted with pores, as well as with the pores filled by conductive material (A2011 alloy, In, or Cu).

Fig. 2 Diagram of sample-magnetic field-optical furnace arrangement and heating energy focus action

The experimental results were compared with the simulations based on the mass amount of each component. Electrical resistivity of the two-component sample was estimated by the following expression:

$$\rho_{1+2} = \frac{\rho_1 C_1}{100} + \frac{\rho_2 C_2}{100}, \quad (2)$$

where ρ_1 and ρ_2 are electrical resistivity of components “1” and “2,” respectively, and C_1 and C_2 are mass concentration of components “1” and “2,” respectively.

Electrical resistivity of the material at the solid state as a function of temperature was determined as follows:

$$\rho_{T_2} = \rho_{T_1} [1 + \alpha (T_2 - T_1)], \quad (3)$$

where ρ_{T_1} and ρ_{T_2} are electrical resistivity at temperatures T_1 and T_2 , respectively, and α is a temperature coefficient of electrical resistivity.

For materials in the liquid state, the electrical resistivity varies with temperature according to the following formula:

$$\rho_e = \alpha T + \beta, \quad (4)$$

where α and β are temperature coefficients for liquid metals and T is an absolute temperature in K. The temperature coefficients were experimentally determined for tested materials (Table 2).

Figure 3 shows a variation of the eddy current induced damping torque values with different oriented pores for A2011 alloy at $T = 23^\circ\text{C}$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹. As expected, the damping torque decreases with porosity in the sample. However, the torque values are slightly (up to 8%) higher for longitudinally oriented holes than for transversely oriented ones. One would assume that in the magnetic field, induced circulating eddy currents, which generate an opposing torque, are weakened by transversal holes more than by longitudinal ones. Using the formula (3), we estimated the electrical conductivity (reciprocal of the electrical resistivity) of the samples, and the results are presented in Fig. 4. As seen from this figure, the measured values of the electrical conductivity are significantly lower (up to 17%) than those predicted. However, the simulations do not consider distribution and orientation of the pores. Hence, we can conclude that the pores distribution and orientation is an important factor, and any future theoretical model must take this into account.

Table 1 Orientation and total volume of pores

Orientation of pores	Diameter of each pore, cm	Volume of sample, cm ³	Total volume of pores, cm ³	Porosity
None	0		0	0
Longitudinal	0.208		0.1294	0.011922
			0.3882	0.035766
			0.6470	0.05961

Fig. 3 Variation of torque with porosity of different orientation for A2011 alloy at $T = 23^\circ\text{C}$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

Fig. 4 Variation of electrical conductivity of A2011 alloy with porosity of different orientation at $T = 23^\circ\text{C}$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

As we know, free electrons are responsible for the electrical and thermal conductivities of metals and alloys in both solid and liquid states. Therefore, the Wiedemann–Franz–Lorenz law can be applied to relate the thermal conductivity to the electrical resistivity:

$$\frac{\lambda \rho_e}{T} = \frac{\pi \kappa^2}{3 e^2} \equiv L_0, \quad (5)$$

where κ is the Boltzmann constant and e is the electron charge. The constant

$$L_0 = \frac{\pi^2 \kappa^2}{3 e^2} = 2.45 \times 10^{-8} \text{ W } \Omega \text{ K}^{-2}$$

is the Lorenz number. The validity of this relationship has been confirmed experimentally with high accuracy by many researchers.^[5–8] A variation of the thermal conductivity estimated by the Wiedemann–Franz–Lorenz law against porosity of different orientation is presented in Fig. 5.

The variations of the electrical resistivity and thermal conductivity of A2011 sample with 4 mm diameter longitudinal hole ($\varphi = 0.0441$) versus temperature are shown in Fig. 6 and 7, respectively. As seen from Fig. 6, electrical resistivity increases almost linearly with temperature. There is good agreement between experimental results and prediction by formula (3).

Fig. 5 Variation of thermal conductivity of A2011 alloy with porosity of different orientation at $T = 23^\circ\text{C}$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

Fig. 6 Variation of electrical resistivity of A2011 alloy (with 4 mm hole) with temperature at $\phi = 0.0441$, $B = 0.1\text{ T}$, and $\omega = 1.05\text{ s}^{-1}$

It is of practical and scientific interest to study the electrical resistivity of immiscible alloys. In this article, we also measured the electrical resistivity of A2011 aluminum alloy with pores filled by indium, A2011 aluminum alloy itself, and copper.

Figs. 8 and 9 represent the experimental values of the electrical resistivity and thermal conductivity over the wide ranges of temperatures for A2011 aluminum alloy sample with 4 mm diameter longitudinal hole ($\phi = 0.0441$) filled by indium. The results of simulations for sample with pores hole and for holes filled by indium are also presented

with these figures. As seen in Fig. 8, the electrical resistivity for sample filled by indium is lower than for sample with pores. Due to the phase transformation in indium at $\sim 150^\circ\text{C}$ (from solid state to liquid), a significant increase in electrical resistivity is observed. Again, the experimental data are lower than those predicted by formula (2), which can be attributed to the effect of the location and orientation of the indium inclusion in the A2011 sample.

One would expect that if the pores were filled by the same material as the sample A2011 aluminum alloy, the electrical resistivity will be recovered to its original

Fig. 7 Variation of thermal conductivity of A2011 alloy (with 4 mm hole) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s $^{-1}$

Fig. 8 Variation of electrical resistivity of A2011 alloy (with and without Indium inclusion) with temperature at $\phi = 0.05961$, $B = 0.1$ T, and $\omega = 1.05$ s $^{-1}$

value for a sample without pores. However, the experiments reveal that the electrical resistivity for samples with holes filled by the same type of metal is higher than that of the original sample. We would suggest that there are additional energy losses on the contact surfaces. The variations of the electrical resistivity and thermal conductivity of A2011 sample with the longitudinal hole ($\phi = 0.0441$) filled by the same metal (A2011) versus temperature are shown in Figs. 10 and 11, respectively.

Figs. 12 and 13 show the variations of the electrical resistivity and thermal conductivity over the wide ranges of temperatures for A2011 aluminum alloy sample with 4 mm diameter longitudinal hole ($\phi = 0.0441$) filled by copper. As seen in Fig. 12, the electrical resistivity for sample filled by copper is higher than predictions made by formula (2). This can again be attributed to the effect of the location and orientation of the copper insertion, and the additional energy losses on the contact surfaces.

Fig. 9 Variation of thermal conductivity of A2011 alloy (with and without Indium inclusion) with temperature at $\phi = 0.05961$, $B = 0.1$ T, and $\omega = 1.05$ s $^{-1}$

Fig. 10 Variation of electrical resistivity of A2011 alloy (with 4 mm hole filled by A2011) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s $^{-1}$

Fig. 11 Variation of thermal conductivity of A2011 alloy (with 4 mm hole filled by A2011) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s $^{-1}$

Fig. 12 Variation of electrical resistivity of A2011 alloy (with 4 mm hole filled by Cu) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

Fig. 13 Variation of thermal conductivity of A2011 alloy (with 4 mm hole filled by Cu) with temperature at $\phi = 0.0441$, $B = 0.1$ T, and $\omega = 1.05$ s⁻¹

CONCLUSIONS

A simple rotational technique to measure the electrical resistivity of molten metals has been applied to study the effect of the porosity formations and different metallic insertions in pure A2011 aluminum alloy. The experimental results revealed the effect of the location and orientation of pores and metallic insertions. Additional energy losses on the contact surfaces resulted in higher

electrical resistivity of samples with insertions compared to predictions.

Molten Metal Processing

Ryotatsu Otsuka

Showa Aluminum Corporation, Sakai-shi, Osaka, Japan

Abstract

Molten metal processing in the aluminum industry and process development has made a great impact on cost performance and quality assurance of aluminum products. This article focuses on molten aluminum refining methods. The topical coverage addresses removal of hydrogen, inclusions and alkali metals from molten aluminum.

Keywords: Alkaline earth metal removal; Dissolved hydrogen; Furnace fluxing; Hydrogen removal; Inclusion removal.

INTRODUCTION

Virgin molten aluminum produced by Hall–Heroult process contains Fe, Si, Zn, Ga, Na as major impurity elements, Ti, V, Mn, Cu, Mg, B as minor one and Al_2O_3 , Al_4C_3 , VB et al. as inclusions. Na is usually removed by Cl_2 gas or $\text{N}_2 + \text{Cl}_2$ gas fluxion into virgin molten aluminum in smelter-based cast house because a few ppm Na in Al-Mg alloy induces cracking during hot working. The primary aluminum produced by smelter is usually about 99.50–99.85% pure, and a small amount of 99.85–99.96% pure aluminum can be produced from a few electrolysis cells operated carefully. Primary aluminum can be refined to 99.990–99.998% purity by three layer electrolysis process in a fused salt mixture. Three layer electrolysis and Na removal treatment are both smelter-based molten aluminum processing. Pure aluminum of 99.99% is mostly utilized as foil material for capacitors. Recently, several segregation (fractional solidification) methods which are superior on cost performance of purification process, have been developed and 99.98–99.996% pure aluminum purified by those solidification processing has come to be utilized for capacitor instead of three layer electrolysis aluminum. Ultra purity aluminum over 99.9990% can be made by zone-melting. Molten primary aluminum for electronic wire is treated by B addition for the purpose of Ti and V removal because Ti and V in solid solution remarkably reduces the electro conductivity of aluminum. Aluminum is very reactive and the chemical reaction between aluminum and water vapor generates hydrogen gas at high temperature. This is the source of hydrogen dissolved into aluminum. Hydrogen solubility in aluminum is determined by an equilibrium relationship between hydrogen concentration in aluminum and hydrogen gas partial pressure in ambient atmosphere. Hydrogen solubility in solid aluminum is far smaller than in liquid

aluminum. Therefore, excess dissolved hydrogen in molten aluminum over solid solubility forms hydrogen gas pores during solidification, or is frozen into super saturated hydrogen solid solution. Excess hydrogen frozen into solid solution heterogeneously precipitates to make gas pores during some heat treatment of cast product. These gas pores impair the strength, ductility and the cutting surface quality of cast product. This is the reason why the melt treatment to remove hydrogen gas is necessary at cast house. The removal of inclusions at cast house is also necessary to assure the quality of aluminum products because inclusions impair the mechanical property and cutting surface quality of the material. Many ways of the melt treatment to remove hydrogen gas and inclusions in aluminum have been developed. Particularly, the development of the process of inert gas dispersion into molten aluminum by a rotating nozzle (Union Carbide is the first developer in 1976) innovated the current way to remove gas and inclusion in the cast house of the aluminum industry, because of its high efficiency, low cost performance and environmental improvement. Filtration method of molten aluminum for inclusion removal has been available from long ago. The technological innovation in this area is due to the development of the new material for filtration such as foamed ceramics and bonded particle media, and the improvement of the reliability of filtration with the development of a quantitative analyzing method for inclusions. The above-mentioned processes of molten aluminum have the same purpose of “Refining.” Grain refining is another type of solidification processing by which fine grain size after solidification can be obtained. Fine grain size is necessary to avoid solidification cracking. Modification treatment by a small amount of Na or Sr addition to Al-Si foundry alloy is necessary to obtain fine eutectic micro structure as solidified. Such a micro alloying effect to cast structure is also observed in intermetallic phases

(Al_xFe_y) appearance of commercial pure aluminum for anodized panels. As mentioned before, several types of molten metal processing such as segregation, grain refining, modification and micro alloying may not be defined as molten metal processing but as solidification processing. So, the author here focuses on the melt treatment for refining such as hydrogen removal, inclusions removal and alkali elements removal from molten aluminum. Molten metal processing plays a very important role in the aluminum industry and the development of new process technology has made a great impact on the cost performance and the quality assurance of aluminum products.

REMOVAL OF DISSOLVED HYDROGEN FROM MOLTEN ALUMINUM

The Source of Dissolved Hydrogen in Molten Aluminum

Only one element of dissolved gas component in aluminum is hydrogen. Hydrogen in molten aluminum (H) has an equilibrium relationship with hydrogen gas in ambient atmosphere.

$$H = \frac{1}{2} H_2(\text{gas}) \quad (1)$$

Equilibrium constant (K_H) of eq. 1 is

$$K_H = \frac{P_{H_2}^{\frac{1}{2}}}{f_H [\%H]} \quad (2)$$

where f_H is the activity coefficient of hydrogen in aluminum, $[\%H]$ is the hydrogen concentration in aluminum and P_{H_2} is the partial pressure of hydrogen gas in the atmosphere. Figure 1^[1] shows the equilibrium hydrogen concentration in pure aluminum with hydrogen gas of 1 bar. (It means the solubility of hydrogen into aluminum under the atmosphere of hydrogen gas partial pressure of 1 atm.) Aluminum reacts with water vapor at high temperature and generates hydrogen gas.

This hydrogen gas is the source of hydrogen in aluminum. In the cast house of aluminum industry they often in humid hot season experience more troubles on cast quality for the dissolved hydrogen in the melt. This is due to the chemical reaction [Eq. 3] between water vapor of higher partial pressure in ambient atmosphere of humid hot season and molten aluminum. TA Engh^[2] proposed the numerical model of hydrogen pick-up from water vapor and he suggests the hydrogen concentration in molten aluminum which is kept for long time under the atmosphere of a constant water vapor pressure (P_{H_2O}) should attain to

Fig. 1 Solubility of hydrogen at 1 atm in 99.9985% pure aluminum^[1]

Fig. 2 The mechanisms for hydrogen dissolution into the molten aluminum from moisture in the atmosphere^[2]

the calculated value. In this model (Fig. 2), at the interface between molten aluminum and atmosphere, Engh looks at various steps involved as follows. Water vapor diffuses through the boundary layer to be adsorbed at the metal surface, the adsorbed molecules reacts with aluminum [Eq. 3], hydrogen molecules are desorbed from the surface, hydrogen molecules diffuse back out of the boundary layer, hydrogen molecules dissociate and form atomic hydrogen on the surface, hydrogen atoms diffuse through the metal boundary layer. By mathematical analysis of each steps using mass transfer coefficients k at gas-melt interface and the equilibrium constant for Eq. 3 in the

surface layer, the partial pressure of hydrogen gas (p_{H_2}) at the interface is given by

$$p_{H_2} = \frac{k_{H_2O}}{k_{H_2}} p_{H_2O} \quad (4)$$

where k_{H_2O} , k_{H_2} are mass transfer coefficients for H_2O , H_2 in gas and p_{H_2O} is the partial pressure of H_2O in the atmosphere. Therefore, the hydrogen concentration in molten aluminum ($[H]_l$) which is kept under the atmosphere of P_{H_2O} for long time is calculated from Eq. 2.

$$[H]_l = \frac{1}{f_H K_H} \sqrt{\frac{k_{H_2O} p_{H_2O}}{k_{H_2}}} \quad (5)$$

The mass transfer coefficients k_{H_2O} and k_{H_2} can be shown to be proportional to the square root of the diffusion coefficients in air, D_{H_2O} and D_{H_2} . Therefore,

$$[H]_l \approx \frac{1}{f_H K_H} \sqrt{p_{H_2O} \sqrt{\frac{D_{H_2O}}{D_{H_2}}}} \quad (6)$$

The diffusion coefficients in air are $D_{H_2O} = 0.239 \text{ cm}^2/\text{sec}$ at 8°C and $D_{H_2} = 0.634 \text{ cm}^2/\text{sec}$ at 0°C .^[3] As a first approximation it is assumed that their ratio do not change significantly with temperature. So, we can obtain Eq. 7.

$$[H]_l \approx \frac{0.783}{K_H} \sqrt{p_{H_2O}} \quad (7)$$

There are few papers^[4-6] which deal with the experimental result of the hydrogen concentration dependence on P_{H_2O} . Otsuka (6) made an experiment to determine the hydrogen pick up of the molten pure aluminum from the water vapor of P_{H_2O} in the ambient atmosphere. Figure 3 shows the experimental apparatus which can keep the molten metal in the atmosphere of a constant partial pressure of the water vapor. The water vapor partial pressure P_{H_2O} was controlled by blowing the dry gas (air or inert gas) of which the dew point is below -60°C through the molecular sieves (in the case of dry air) or the humidified gas through the pure water into the stainless steel box, and the value of P_{H_2O} above the melt surface was determined by the measurement of the dew point of the gas blew out of near the melt surface in the box.

Fig. 3 The experimental apparatus for the investigation of hydrogen dissolution into the molten aluminum in the high purity alumina crucible (inner dia. 80 mm, inner height 170 mm) from moisture in the atmosphere^[6]

Fig. 4 Hydrogen concentration change in molten 99.99% Al at 700°C under the dry air atmosphere of $P_{\text{H}_2\text{O}} = 1.7 \times 10^{-4} \text{ atm}$ ^[6]

The temperature of the melts were controlled to $675 \pm 5^\circ\text{C}$, $700 \pm 5^\circ\text{C}$ or $750 \pm 5^\circ\text{C}$. The molten aluminum of 99.99% pure in the high purity alumina crucible (inner dia 80 mm, height 170 mm) was held in stationary state or stirred state by the rotating graphite impeller (dia. 45 mm, height 30 mm) at 530 rpm. The hydrogen concentrations of the molten aluminum before and after the treatments were measured by the nitrogen fusion method (I THAC-2002 manufactured by ADAMEL LHOMARGY was used.) for the carefully machined cylindrical samples from the ingots solidified into the Ransley's mould. Figure 4 shows the experimental result of the hydrogen concentration change in the molten pure aluminum which was held at 700°C in the dry air atmosphere with $1.7 \times 10^{-4} \text{ atm}$ of $p_{\text{H}_2\text{O}}$ ($p_{\text{H}_2\text{O}}$ in the usual air in Japan is about $1.5 \times 10^{-3} - 3.0 \times 10^{-2} \text{ atm}$). The hydrogen concentration of the stationary melt slowly decreases, and after long time holding more than 300 min it looks like to attain a constant value which may be same as the equilibrium value of hydrogen concentration ($0.07 \frac{\text{ml}}{100\text{g}} = 0.07 \text{ p.p.m.}$) which had been attained after about 50 min holding while stirring the melt by rotating impeller. Figure 5 shows the time dependence of the hydrogen concentration in the stirred molten aluminum under the air atmospheres containing various amounts of water vapor. The hydrogen concentration of molten aluminum attains to the equilibrium value depending on $P_{\text{H}_2\text{O}}$ irrespective of whether the initial hydrogen concentration is lower or higher than the equilibrium one. The relationships between $P_{\text{H}_2\text{O}}$ and the attained equilibrium hydrogen concentration ($[H_e]_{\text{ml}/100\text{g}}$) at 675°C, 700°C and 750°C are nearly linear on log-log scale when $P_{\text{H}_2\text{O}}$ is below $1.7 \times 10^{-2} \text{ atm}$ as shown in Fig. 6. The correlative equations calculated are as follows.

At 675°C

$$[H_e] = 3.17 p_{\text{H}_2\text{O}}^{0.470} \quad (8)$$

At 700°C

$$[H_e] = 3.49 p_{\text{H}_2\text{O}}^{0.453} \quad (9)$$

At 750°C

$$[H_e] = 3.16 p_{\text{H}_2\text{O}}^{0.387} \quad (10)$$

Figure 7 shows the linear relationship between $\log [H_e]$ and $1000/T$ (T is the temperature of melt) at the constant value of $P_{\text{H}_2\text{O}}$. The activation energy of hydrogen solution from water vapor was calculated to be 38806 cal/mol, 30977 cal/mol and 19467 cal/mol on each case of 1.0×10^{-2} , 10^{-3} and 10^{-4} atm of $P_{\text{H}_2\text{O}}$. They are in rough agreement with the activation energy of hydrogen solution from hydrogen gas, 28258 cal/mol.^[7] These experimental result suggests the pickup of hydrogen from water vapor may occur by the model proposed by Engh and it is limited by slow mass transfer of hydrogen in molten aluminum to the surface, although these experimental values of the equilibrium hydrogen concentration is larger than the calculated value by Eq. 7. It is supposed the oxide film of molten aluminum surface may affect the hydrogen pick up of molten aluminum, because the equilibrium hydrogen concentration with $P_{\text{H}_2\text{O}}$ in inert gas atmosphere of N_2 or Ar is lower than in air atmosphere and it is attained earlier than in air atmosphere as shown in Fig. 8.

The Principle of Hydrogen Removal from Molten Aluminum

The removal of hydrogen from molten aluminum is based on the equilibrium relationship between the hydrogen in molten aluminum and the hydrogen partial pressure in ambient atmosphere as Eq. 2. That is

$$[\%H] = \frac{K_H}{f_H} \sqrt{p_{\text{H}_2}}$$

Fig. 5 The time dependence of hydrogen concentration in stirred melt of 99.99% Al under the air atmospheres containing various amounts of water vapor^[6]

Fig. 6 The relationships between $\log[H]_c$ and $\log P_{\text{H}_2\text{O}}$ ^[6]

Fig. 7 The relationships between $\log[H]_c$ and $1000/T$ ^[6]

Fig. 8 The time dependence of hydrogen concentration in stirred melt of 99.99% Al under the inert gas atmospheres containing various amounts of water vapor

It means that when the molten aluminum is kept under the inert gas atmosphere, in the vacuum in both of which $P_{H_2} = 0$ is formed, or injected inert gas bubbles which have no hydrogen gas ($P_{H_2} = 0$) before the injection, the hydrogen in the molten aluminum diffuses to the melt surface and transfers to the gas or the vacuum. The activity coefficient of hydrogen f_H ($f_H = 1$ for pure aluminum) may change with alloying elements such as Si, Cu, and Mg.

Table 1 Calculated values of hydrogen activity coefficient (f_H) in molten aluminum alloys^[10]

Alloy	f_H
Pure Al	1.00
AA No. 6063 (Al-0.6% Mg-0.4% Si)	1.01
AA No. 3003 (Al-1.2% Mn-0.2% Si)	1.21
JIS AC7A (Al-5.0% Mg-0.4% Mn)	0.94
JIS AC8C (Al-11% Si-2.9% Cu-1.2% Mg)	2.03
AA No. 5052 (Al-2.5% Mg-0.2% Cr)	0.94
AA No. 6061 (Al-1.0% Mg-0.6% Si-0.2% Cu)	1.03
AA No. 1100 (Al-0.55% Fe-0.13% Si)	1.04
AA No. 2017 (Al-3.8% Cu-0.7% Mg-0.5% Si-0.7% Mn)	1.46

Therefore, the solubility of hydrogen in pure aluminum may be different from aluminum alloy and the easiness of hydrogen removal will depend on alloy species. The value of f_H for an alloy can be estimated by the calculation using interaction coefficients in liquid Al-H-i alloys.^[8,9] Table 1 shows the calculated f_H of several molten alloys.^[10] As shown in Eq. 7 or Eqs. 8, 9 and 10, it is also very important for the hydrogen removal that the hydrogen pick up from water vapor should be avoided. Then, in the molten metal processing for hydrogen removal, the water vapor partial pressure in the atmosphere, the purge gas and the crucible material must be as small as possible.

The Molten Metal Processing for Hydrogen Removal

The current worldwide technology for hydrogen removal from molten aluminum is the inert gas purging method by rotating nozzle. In the history of aluminum industry, Cl₂ or Cl₂ + N₂ gas purging by lance pipe was the usual way for hydrogen removal. It is clear from the thermodynamic calculation of the Gibbs energy change of the chemical reaction between Cl₂ and H in the melt that Cl₂ gas does not react with

H in molten aluminum to give HCl (gas) but reacts with molten aluminum to give AlCl₃ (gas above 183°C). They

might have thought Cl_2 gas purging is effective for hydrogen removal due to HCl formation, but the mechanism of hydrogen removal is only due to hydrogen diffusing out of molten aluminum into AlCl_3 gas bubbles, similarly as in the case of inert gas purging into molten aluminum. However, it should be noticed the size of gas bubbles in molten aluminum from lance pipe is smaller in the case of Cl_2 gas purging in comparison with inert gas purging, and it may be due to the reduction of gas-metal surface tension in the case of AlCl_3 gas and the high heat of formation of AlCl_3 gas.^[11]

As described later, Cl_2 gas is effective on the removal of Na and oxide inclusion from molten aluminum. However, because of air pollution by Cl_2 , N_2 gas purging for hydrogen removal was investigated instead of Cl_2 and gas purging by porous plug to give fine gas bubbles into molten aluminum was tried for the improvement of hydrogen removal efficiency. The efficiency of hydrogen removal by the inert gas purging have been drastically improved since the first inert gas dispersion process into molten aluminum by spinning nozzle (SNIF) had been developed in 1976.^[11] The gas dispersion into molten aluminum by SNIF is schematically shown in Fig. 9. The gas injection apparatus (U.S. Pat. 3743263, 1973) of SNIF is comprised of a stationary sleeve and a vaned rotor. The shaft driving an impeller is surrounded by a stationary sleeve. The lower part of the sleeve is expanded into a stator head which is partly slotted at regular intervals. Metal penetration is prevented by the pressure of the sparging gas. This gas enters the molten aluminum through a clearance between stator and impeller (rotor). The small gas bubbles (1–10 mm) produced by shear and collision with the vanes of the rotor are uniformly dispersed in the entire body of the metal. The efficiency of degassing depends on the inert gas-metal interfacial area and the inert gas-metal contact time. The minimum inert gas consumption which means maximum efficiency can be approached by providing a high specific interfacial area (surface to volume ratio) and sufficiently long contact time. SNIF can disperse far smaller sizes and larger numbers of bubbles than porous plugs, and the inert gas atmosphere of

Fig. 9 Ar gas bubbles dispersion into molten aluminum by SNIF rotor^[11]

Fig. 10 SNIF in-line apparatus^[11]

a positive pressure relative to the ambient pressure in the closed chamber prevents the infusion of water vapor into the chamber. Figure 10 shows the apparatus of SNIF for in-line refining which is located between holding furnace and casting station in the cast house of aluminum rolling company. Sigworth and Engh^[8] presented a mathematical analysis of the kinetics of hydrogen removal by inert gas purging. Engh and Pedersen,^[12] and Engh^[13] presented a model of hydrogen removal from molten aluminum by gas purging which includes hydrogen pick up from humidity (water vapor) above the melt. That is, Reduction of content of hydrogen in batch (not in-line) = Hydrogen transferred to bubbles + Hydrogen transferred to atmosphere at bath surface. The theory (calculated result) was compared with the experimental result of the hydrogen removal for Al-7%Si-0.5% Mg in a 200kg furnace using lance, porous plug and spinning nozzle (SNIF). It is shown in Fig. 11. Figure 12 shows the calculated curves of hydrogen removal by spinning nozzle with different melt surface conditions of hydrogen pick up. The surface completely exposed to air picks up hydrogen from water vapor as was given in “The

Fig. 11 Hydrogen removal by gas purging with lance, porous plug and impeller in 200kg melt of Al-7% Si-0.5% Mg for the same gas flow (6 l/min)^[12]

Fig. 12 Calculated curves for hydrogen removal with. (a) surface completely exposed against air; (b) a lid; (c) blowing inert gas on the surface (combined with a lid)^[12]

Source of Dissolved Hydrogen in Molten Aluminum” section. When the atmosphere above the melt is covered with a lid, there should be little or no hydrogen pickup from the air. When the surface is blown by inert gas, $[\%H]_i \approx 0$ (see Eq. 5). Those calculated curves suggest SNIF can decrease the hydrogen concentration in molten aluminum to be below 0.01 ppm (0.011 ml/100g), however, actually, the hydrogen concentration cannot be decreased below 0.05 ppm.

Usually it is very difficult to remove moisture perfectly from the atmosphere in the chamber because of the difficulty for perfect sealing (preventing air penetration) and the difficulty for the removal of the moisture adhered physically or chemically to the material of the chamber or the crucible. In the case of SNIF the inlet of molten aluminum is not sealed and a little amount of air can enter into the chamber even if a positive pressure of inert gas atmosphere

is effective to prevent air infusion from the ambient atmosphere (see Fig. 10). That is the reason why the actual result differs from the calculated result. SNIF can also remove solid particles from molten metal by flotation^[11] as described later and it was the innovative refining process for molten aluminum. However, it is a sophisticated and big apparatus (big holding capacity of molten metal in the reactor is necessary for in-line melt treatment.) which is suitable for the refining of a large amount of one species of molten alloy without changing the species of molten alloy in the chamber. Therefore, SNIF was installed mainly in the cast house for a large amount of can body sheet alloy (AA No. 3004) which should be enough refined to remove gas and inclusion in order to obtain high ductility in sheet-forming (drawing). After SNIF, Pechiney and Showa have developed new refining processes by rotating gas injector, AlPur (Fr. Patent no. 8116735) and GBF (U.S. Patent 4611790, 1986). The rotor and the treatment box of AlPur are shown in Fig. 13. AlPur in-line process has a tilting device for emptying the box in order to be easy for the change of molten metal refined and simple system for cleaning by dross removal (to open the lid).

The degassing efficiency of AlPur in-line process $([\%H]_{\text{inlet}} - [\%H]_{\text{outlet}}) / [\%H]_{\text{inlet}}$ depends on inert gas (gas injected) flow rate and rotating speed (100–250rpm) of gas injector as shown in Fig. 14.^[14] In inert gas dispersion process the real efficiency of gas removal should be evaluated both by the reduction rate and the attainable minimum hydrogen content under the atmosphere which has $p_{\text{H}_2\text{O}}$ of water vapor partial pressure above the melt surface. GBF which is a molten metal processing under the air atmosphere has been developed by studying chemical engineering for effective chemical reaction between gas and liquid. Figure 15 shows dispersed bubbles around rotating cylinder in the water (Jap. Pat.

Fig. 13 AlPur rotary mixer and treatment boxes^[14]

Fig. 14 Degassing efficiency curves by ALPur rotary mixer; dependence on inert gas flow rate and rotating speed^[14]

Fig. 15 N₂ gas bubbles dispersion in water by rotating cylinder (diameter = 50 mm, height = 80 mm, rotating speed = 1000 rpm)^[10]

529603). Large spherical cap bubbles circulate and ascend around the rotating cylinder, and near the half height of the cylinder they look to be finely dispersed centrifugally after being sucked to the cylinder surface. Water flow pattern around the rotating cylinder as shown in Fig. 16 looks to be same as typical flow pattern in baffled tank with turbine positioned on center.^[15] It is revealed that bubbles on water flow is finely torn off by a vigorous turbulent flow toward centrifugal direction near the half height of the cylinder surface where down and upward flow collide with. It was found small height and large radius of cylinder, positioned near bottom was effective for more fine dispersion of

Fig. 16 Flow pattern of water by rotating cylinder^[10]

Fig. 17 Schematic diagram of GBF method^[10]

bubbles, and a practical rotor (Jap. Pat. 1375860) as shown in Fig. 17 has been developed after many trials of various disk-like rotors. Figure 18 shows dispersed bubbles in the water by GBF rotating injector. Bubble size is small (1–4 mm dia.) and bubble dispersion is uniform throughout the water. Assuming bubble size in molten aluminum is nearly twice in water as Engh et al.^[12] described, the size

Fig. 18 Ar gas bubbles dispersion into water by rotating GBF nozzle^[10]

Fig. 19 Hydrogen removal from molten Al-7% Si-0.3% Mg alloy by GBF treatment and hydrogen removal from Al-7% Si-0.5% Mg by SNIF nozzle or porous plug^[10,12]

of dispersed bubbles into the melt by GBF may be about 2–8 mm diameter.

Baffle plate shown in Fig. 17 suppresses circulative flow and vortex around rotating shaft to form upward flow near baffle. Baffle plate is effective for mixing of the melt and the flotation of inclusion by forced upward flow as described later. Figure 19 shows the hydrogen removal result from molten Al-7% Si-0.3% Mg by GBF under the air atmosphere in which $p_{\text{H}_2\text{O}}$ is 1.0×10^{-2} – 1.5×10^{-2} atm (500kg of molten metal, 20 l/min of Ar flow rate). The result by SNIF nozzle and porous plug in Fig. 11 was also shown in Fig. 19 for the comparison of hydrogen removal effect, although Ar flow ratio is 0.4 l/min per kg molten metal (GBF) and 0.3 l/min per kg molten metal (SNIF). The influence of $p_{\text{H}_2\text{O}}$ in the ambient air atmosphere to the hydrogen removal by GBF was examined by the experimental apparatus as shown in Fig. 20. The value $p_{\text{H}_2\text{O}}$ in the box of the apparatus

Fig. 20 Experimental apparatus for GBF melt treatment in conditioned atmosphere of optional partial pressure of water vapor ($P_{\text{H}_2\text{O}}$)^[10]

Fig. 21 Hydrogen removal from molten 99.99% Al by GBF treatment in the several air atmospheres of different water vapor partial pressures ($P_{\text{H}_2\text{O}}$)^[10]

controlled by the flow rate of the dry air of which the dew point was below -60°C through the molecular sieves. The result for 99.99% Al is shown in Fig. 21. On the production of 99.99% Al foil for capacitor, hydrogen gas pores (Fig. 22) in casted slab after homogenization heat treatment at 600°C may be the origin for the cracking during hot rolling. Such pores in high purity aluminum ingot are formed by the annihilation of micro porosities (which may involve hydrogen gas) and the precipitation of excess hydrogen over the solubility (0.03 ml/100 g at 600°C)^[1] at the grain

Fig. 22 Development of hydrogen gas porosity in 99.99% Al ingot by homogenization heat treatment in air atmosphere of $P_{H_2O} = 3 \times 10^{-2}$ atm (a) before heating; (b) 600°C, 1 h; (c) 600°C, 4 h; (d) 600°C, 12 h

Fig. 23 Hydrogen removal from molten Al alloys by GBF treatment in air atmosphere of $P_{H_2O} = 5.0 \times 10^{-3}$ to 7.5×10^{-3} atm^[10]

boundary which may disappear or rearrange by recrystallization during homogenization heat treatment. It is known by our experience that the hydrogen content which does not induce hot cracking should be below 0.10 ml/100g. Therefore, the hydrogen removal from 99.99% Al by GBF must be

done under the dry air atmosphere of dew point below -6°C ($P_{H_2O} < 3.8 \times 10^{-3}$ atm). Hydrogen removal result for several alloys by GBF under near the same air atmosphere of P_{H_2O} is shown in Fig. 23 (AC7A and AC8C by Japan Industrial Standard are the casting alloys of Al-5.0% Mg-0.4% Mn and Al-11% Si-2.9% Cu-1.2% Mg, and 3003 by AA No. is Al-1.2% Mn-0.2% Si-0.1% Cu.) and in Fig. 24 (5052, 6061, 1100 and 2017 by AA No. are Al-2.5% Mg-0.2% Cr, Al-1.0% Mg-0.6% Si-0.2% Cu, Al-0.55% Fe and Al-3.8% Cu-0.7% Mg-0.5% Si-0.7% Mn.) The attainable hydrogen reduction level of each alloy by GBF seems to depend on the activity coefficient of hydrogen in molten aluminum alloy which was estimated as shown in Table 1 in “The Principle of Hydrogen Removal from Molten Aluminum” section (Fig. 25). One of the unexpected results by hydrogen removal by GBF in-line treatment revealed the surface improvement of AA No. 6063 alloy billet by semi-continuous casting as shown in Fig. 26. It should be noticed from this figure that such a smooth cast surface could be obtained by the removal of hydrogen and inclusions from molten aluminum and not obtained only by inclusions removal by RMF filtration described in “Rigid Porous Media Tube Filter-RMF” section. Several inert gas purging methods by rotating a nozzle other than SNIF, AlPur and GBF have been developed.^[116–18]

Table 2 Inclusions in aluminum^[19,20]

Particle type	Particle phase and source	Particle shape	Size (dia.) range (microns)
Oxides	Al_2O_3 from oxidation of melt surface	films or group of films	10–1000
	Al_2O_3 from undissolved Alumina	polygonal particles	10–20
	Al_2MgO_4 from oxidation of melt surface	truncated pyramidical particles	0.1–5
		thick films or lumps	1–100
	MgO from oxidation of melt surface or alloying additions	polygonal particles	0.2–1
	Refractory brick (Al, Si, O)	films consisting of particles	10–1000
Carbides	Al_4C_3 from Hall-Heroult cell	lumps or particles	10–500
Borides	TiB_2 , VB from Hall-Heroult cell	rectangular or hexagonal discs	0.5–25
	TiB_2 from grain refiner	rectangular or hexagonal discs	1
		discs	1–3
		clusters of discs	1–50
Salts	Cryolite (Na_3AlF_6) from Hall-Heroult cell	spheres	10–20
	Mg/Al chlorides from Cl_2 gas fluxing or dross fluxing		
	Na/K chlorides from dross fluxing		

REMOVAL OF INCLUSIONS FROM MOLTEN ALUMINUM

Inclusions in Molten Aluminum

Typical inclusions in molten aluminum are shown in Table 2. The source of inclusions is from Hall–Heroult cells of smelters and melting–casting process in all of aluminum industry. Inclusions mean solid particles in melt which are nonmetallic compound such as oxide, carbide and salt (strictly, some salts are liquid sphere in molten aluminum, for example, the melting point of $MgCl_2$ is $712^\circ C$), and intermetallic compound of high melting point such as TiB_2 . Concentration of inclusions in aluminum usually is below 1 ppm except Al_4C_3 from Hall–Heroult cell and TiB_2 from grain refiner addition. The detrimental effect of inclusions to the properties of aluminum products appears generally on the size beyond 30 microns. Recently the rigorous drawing and ironing of 3004 alloy sheet for the thin wall can body and the high grade polishing surface for computer memory disks request the removal of smaller inclusions. In the case of very thin foil of few microns, inclusions below 10 micrometers in size may be the origin of pin-hole defects. Figure 27 shows microscopic photographs of typical inclusions found in a molten aluminum alloy.

The Principle of Inclusion Removal from Molten Aluminum

Floatation

The floatation of solid particles from molten aluminum by the dispersed gas bubbles of SNIF process was

Fig. 27 Inclusions observed in AA No. 6063 alloy melt before refining processing. Molten metal sample was filtrated through porous carbon plate and filtrated inclusions were analyzed by XMA. (a) gray small particles; Ti-B compound, black fine particles; Al_4C_3 , black film; Al_2O_3 ; (b) cluster of fine particles; MgO including Al_2MgO_4 , black particles; Al_4C_3

Fig. 28 Inertial impact of particles on gas bubbles^[11]

investigated on theoretical fluid dynamics by A.G. Szekely.^[11] Two mechanisms of floatation, i.e. inertial impaction and peripheral interception, were proposed. Inertial impaction on gas bubbles is shown in Fig. 28. The stream lines of the fluid are diverted by the sphere irrespective of whether the body is stagnant and the fluid medium is flowing or the medium is stagnant and the body is moving. The curved streamlines (shown by the thin lines on the sketch) prevent the frontal collision of small particles with the sphere. Large particles can, however, establish their own paths by inertia which are distinct from the stream lines of the fluid. The possible paths of such large particles are illustrated by the dashed lines. The interception of the path of a large particle by the sphere is still not guaranteed, but only those particles which are present originally in the fluid bounded by the heavy lines have chance to contact the spherical body (where the mass and velocity of particles a_1 and a_2 may be equal for example).

The number of these particles related to the total number of particles enclosed in a liquid column which has

a diameter equal to the diameter of the sphere defines a contact efficiency which can be calculated if the velocity distribution and the trajectories of the particles are known. The size of the smallest particles which can be collected by inertial impaction on gas bubbles was calculated for oxide particles suspended in molten aluminum based on theoretical fluid dynamics. This calculation leads to the conclusion that all particles larger than about $80 \mu\text{m}$ can be collected from molten aluminum by inertial impaction on gas bubbles if the size of the bubbles is in the 1–10 mm range.

Small particles which are completely entrained by the stream lines of the fluid due to their small masses have a poor chance of colliding with rising gas bubbles. However, those particles can establish contact with the bubbles which are brought within a touching distance to the bubble around its equator by the streamlines of the liquid (Fig. 29). Peripheral interception is the second mechanism for floatation. The efficiency of such a peripheral contact between a gas bubble and solid particles was approximated by the simple geometric argument considering a hypothetical bubble column of $r^2\pi$ base containing n_0 number of particles at uniform distribution. Only those particles of radius a which are carried into the equatorial ring of $2a$ width of the bubble can skirt the bubble. In a decrease of the particle concentration of $\Delta n_0 = n_0 - n_0/x$, the decrease of the particle concentration due to peripheral interception by gas bubbles is expressed by Eq. 11 for gas sparging rate $G \text{ m}^3/\text{kg}$.

$$x = \exp(54 \times 10^4 G \times a / r^2) \quad (11)$$

or for typical gas sparging rate ($7.8 \times 10^{-4} \text{ m}^3/\text{kg}$) in the SNIF process

$$x = \exp(12 \times a / r^2) \quad (12)$$

Fig. 29 Peripheral interception of particles by gas bubbles^[11]

Fig. 30 Flotation of particles at a gas sparging rate of $7.8 \times 10^{-4} \text{ m}^3/\text{kg}$ as calculated from Eq. 10^[11]

The solution of this equation for 1–10 mm gas bubbles is shown in Fig. 30. From this figure it is important to produce gas bubbles as small as possible to assure a satisfactory removal of particles from the micrometer range and is nearly impossible to remove inclusions of submicron size by 2–10 mm bubble. Szekely presented also the theory of agglomeration and the agglomeration of solid particles in molten aluminum in the SNIF process for the removal of submicron size inclusions. Small solid particles suspended in a liquid move in a random, chaotic fashion as a result of the Brownian movement. If the size of the particles is in the micrometer and smaller range the collision of the particles inevitably leads to their coagulation due to the high specific surface energies of such small particles. This is thermal agglomeration. It is shown that the frequency of collision of particles in a given liquid is a single valued function of the temperature. In case the movement of the particles is enhanced by turbulent energy, the frequency of collision and the resulting coagulation rate of the particles can be significantly higher than due to thermal energy alone. This is turbulent agglomeration. The chaotic movement of the particles is sensitive to the scale of the turbulent eddies in which the movement of the particles is truly erratic. Large scale eddies have no significant effect on the collision of small particles and such eddies only stir the suspension, keeping the distribution of the particles uniform in the liquid. With diminishing eddies a certain scale is reached where the acceleration of the fluid in the eddies is at a maximum. The scale of such eddies is called the inner scale of turbulence. Below this critical scale, the kinetic energy of turbulence is gradually converted into heat due to the viscous resistance of the fluid. If particles are present in the fluid, the force exerted by the high acceleration present in such critical eddies pushes the particles randomly around causing them to collide with each other. The movement of the particles can be related under this condition to the volumetric dissipation rate of turbulent energy ϵ which is independent of the scale of motion and is a characteristic constant for a given flow. The constant of turbulent coagulation is shown to be proportional to $\sqrt{\epsilon}$.

This is applicable to particles not larger than about $10 \mu\text{m}$ since the inner scale of turbulence is of the order of $10\text{--}100 \mu\text{m}$ in vigorously stirred liquid. The volumetric dissipation rate of energy ϵ can be calculated from macroscopic parameters, such as from the size and speed of an impeller creating the macroscopic turbulence, or from the power utilized in the SNIF process for stirring a given melt volume. By the ratio of the calculated constants of turbulent and Brownian coagulation it is shown that particles less than about $0.1 \mu\text{m}$ agglomerate predominantly due to their Brownian movement, while particles larger than that agglomerate faster by turbulence at the typical power inputs in the SNIF process. Experimental result of thermal and turbulent agglomeration of solid particles in molten aluminum has not yet been presented, but agglomeration of $10 \mu\text{m}$ SiC and Al_2O_3 in electromagnetically stirred molten aluminum was presented.^[21] In this study, most of the initial $10 \mu\text{m}$ particles disappeared from the melt to form clusters in less than 1 minute and no cluster bigger than $100 \mu\text{m}$ was observed.

Settling

Inclusions heavier than the melt may sink and inclusions lighter than the melt may float up in the melt. Heavy inclusions in stagnant molten aluminum accumulate as a slurry in the lower part of the melt while light inclusions collect near the melt surface to form dross with oxide film. The term “settling” is used both when particles sink or float up. The fundamental equation governing “settling” of small particles in a melt is the drag force on the particle sphere by Stokes Law. Drag force on a particle sphere of radius r in homogeneous flow of velocity V is

$$D = C_d \left(\frac{\rho V^2}{2} \right) (\pi r^2)$$

where C_d is empirical friction factor and ρ is the density of the particle. When Reynolds number $R (R = rV\rho/\mu)$ is so small that viscous force on a particle far exceed inertial forces, $D = 6\pi\mu Vr$ and $C_d = 12/R$ where μ is viscosity. If we assume the particle settles at constant terminal velocity (V_∞) in the melt, the difference between gravity and buoyancy force on the particle balances.

$$\Delta\rho g \left(\frac{4\pi r^3}{3} \right) = 6\pi\mu V_\infty r$$

So

$$V_\infty = \frac{\Delta\rho g r^2}{18\mu} \quad (13)$$

Filtration

The mechanism of molten aluminum filtration for the removal of inclusions involves cake mode filtration and deep bed filtration.^[22–24]

Cake Filtration A rudimentary example of cake mode filtration is the fiberglass screen of trough sock or spout sock used for the removal of large inclusions. Reticulated ceramic foam plates and consolidated rigid media are commercial examples of cake mode filters (and also of depth mode filters as described later). Particles larger in size than the filter pores are strained on the surface of the filter medium. Through the depth of the filter medium particles are also trapped wherever a flow channel is smaller than the particle. As a layer of separated particles is deposited, the effective opening diameter is progressively decreased. Smaller diameter inclusion particles can now be captured in subsequent layers of separated solids, thus forming a cake. A thick layer of particles accumulates above the filter medium with little or no penetration into the internal pore structure. The resulting filter cake leads to high filtration pressure (high pressure drop) and a limited filter capacity.

Depth Filtration Typical examples of depth filtration are deep bed filters such as Alcoa 94^[25] Alcoa 469^[26] and tubular cartridge filter comprised of rigid media.^[27] On the case of depth filtration, particles are deposited through the depth of the filter medium, even though they are much smaller in size than the filter pore flow channels. Capture process in depth filtration involves two steps which are the transfer of inclusion from the bulk metal to the surface layer of the filter substrate and the adhesion of inclusion at a retention site on the filter substrate. Transfer processes are classified as follows.^[23,24]

Sedimentation or floatation; if the inclusions have a density different from that of liquid, they can be transported to the filter media away from fluid line by gravity or buoyancy. Inertia; owing to their apparent weight, inclusions cannot follow the same trajectory as that of the fluid. When the direction of the fluid flow changes suddenly, inclusions can deviate from the fluid flow path and be transported to the filter media. Hydrodynamic effects; owing to non-uniform velocity profile of fluid flow and non-spherical shape of inclusions, they may be moved laterally to the filter media by hydrodynamic effects. Direct interception; even with exactly the same density as the fluid, owing to their size, particles would not be able to follow the smallest tortuosities of the fluid flow line and they may collide directly with the filter media. Effects of turbulence; in turbulent flow, particles may be carried to the filter media. For the adhesion of inclusions on the substrate of filter, several forces can be exerted as follows. Fluid pressure; the pressure of the flowing fluid may hold the inclusions at the site of filter surface where they have been transferred. Friction; inclusions can be held at the site of filter surface by friction. Physicochemical; physical or chemical adhesion by Van der Waals force or chemical bonding may hold the inclusions at the site of filter surface in molten aluminum.

The Molten Metal Processing for Inclusions Removal

Floatation Method by Gas Purging

Several results of inclusion removal by SNIF were reported. The removal of oxides was investigated by refining the melt with a higher inclusion content.^[28] Size distribution of oxide inclusions observed by light microscopy analysis revealed that inclusions larger than 50 μm in cross section were removed, as shown in Fig. 31.

The removal of borides was also measured and the result revealed that none or very little of the borides were removed by SNIF. TiB_2 in Al-Ti-B grain refining master alloy for controlling the as-cast grain size acts as nucleant and it has good wetting to molten aluminum. So TiB_2 is difficult to be separated from molten aluminum by gas purging. It should be noticed we can add Al-Ti-B master alloy into the molten aluminum before the melt treatment by gas purging such as SNIF, AlPur and GBF, but we cannot do that before the filtration which is able to remove TiB_2 particles. An evaluation of a SNIF unit for inclusion removal in mass production lines revealed that inclusion removal efficiency depended on incoming inclusions concentration and Cl_2 mixing in purging gas might be effective as shown in Fig. 32.^[29] We have observed that the gas purging of Cl_2 or inert gas/ Cl_2 mixtures by rotary nozzle forms less quantity of dross on the melt surface than in the case of inert gas purging. Furthermore, the dross is dry. That is different from wet dross in the case of inert gas purging. Where dry dross means more separated inclusions (mainly

Fig. 31 Size distribution (by number) of sedimented oxides in samples from the original melt and the melt refined by SNIF. The analysis was performed by the centrifugation method, and the diameter d is the maximum diameter of the oxide films^[28]

Fig. 32 Incoming inclusions versus SNIF efficiency^[29]

oxides) agglomeration from molten metal than in the case of wet dross. The mechanism of such a phenomena is not well known although the large heat of AlCl_3 formation may relate to it. Recently, SNIF SHEER system^[30] incorporated changes to the chambers and the nozzles which increased the efficiency of the system (See Fig. 33).

A rib was added to the bottom of the chamber and it was useful to stabilize and equalize the metal flow pattern within the chamber. The action of the rib is supposed to be similar to one of the baffle plate of GBF process. It was demonstrated the SHEER system removed 20% more hydrogen with 22% less process gas in comparison with current SNIF system. However, differences in inclusion removal could not be detected because of the large variability in the inclusion measurements. The high efficiency of inclusions removal by GBF may be supported by forced upward flow of molten metal by both the actions of rotating impeller and baffle plate. Actually, it

Fig. 33 Cross-section of a SNIF SHEER R-140 system^[30]

Fig. 34 Inclusion inspection of stainless wire cloth (500 μm dia. and 200 μm dia.) after being dipped into and moved in molten metal. (a) Original melt of AA No. 5056; (b) after 6 min of GBF treatment

was revealed the dross (the agglomeration of inclusions such as oxide film etc. and molten metal) floatation on the melt surface by the gas dispersion from the rotating injector of GBF was drastically accelerated by the baffle plate. Several results for inclusion removal by floatation were presented for GBF. The most apparent result for the large inclusions removal from AA No. 5056 alloy melt by 3 min. of GBF treatment was presented by the

inspection of stainless wire cloth (500 μm dia. pore) after being dipped into and moved in molten metal as shown in Fig. 34.^[31,32] In this figure, the convex surface of metal film shows the presence of inclusion. The inside of these convex sections were microscopically observed and it was revealed that oxide inclusions were not wetted by molten metal. In Fig. 35, the evaluation of GBF for the removal of aluminum oxide inclusions (aluminum oxide particles of 10–30 μm dia. were added by about 1 vol% into molten pure aluminum and the melt was treated for 10 min by GBF) is presented by the microscopic observation of the sample filtrated by porous carbon of 50–100 μm in pore size.^[33] Showa Aluminum (Japan) produces foil including high purity foil (99.99% Al) for capacitor, sheet of AA No. 1000 series and 5052 alloy, and extrusion of almost all species of alloys. 8 in-line GBF units were installed between the holding furnaces and the casting stations in all the cast shops of Showa. The effect of both hydrogen and inclusion removal by GBF revealed notable yield improvement of foil, sheet and extrusion by the decrease of the number of defects such as pinhole, scratch like stringer, and blister etc.

Settling

Although it has long been recognized the holding time (that is to say killing time) after Cl_2 gas fluxing into molten aluminum is necessary for inclusions to be settled out, its quantitative study was not possible until several methods of quantitative analysis for inclusions such as PoDFA^[34] and LiMCA^[35] had been developed. A result of settling measured by PoDFA and LiMCA revealed the settling curve could be represented by the simple exponential decay function as shown in Fig. 36.^[36] Molten primary aluminum for electric wire is treated by B addition and stirring the melt for the purpose of the removal of Ti and V. The chemical reaction between (Ti, V) and B in molten aluminum forms high melting point intermetallic compound, TiB_2 and VB_2 . TiB_2 and VB_2 agglomerates to form $(\text{Ti V})\text{B}_2$ particles. By the settling of $(\text{Ti V})\text{B}_2$ particles as shown in Fig. 37,^[35] Ti and V in molten aluminum could be removed.

Filtration

Ceramic Foam Filtration-CFF Ceramic foam plate (2 in thickness, 7–23 in square) is produced by using a polymeric foam precursor which is immersed in a ceramic slurry, squeezed to remove any excess and is then fired. Three- and two-dimensional images of the ceramic foam is as shown in Fig. 38.^[37] A rough characterization of the structure of the ceramic foam is given by the number of pores per inch (ppi) and commercial filter grades are 10–50 ppi. The grade of 10 ppi has 3800 μm of minimum cell size and 5100 μm of maximum cell size. The grade of 50 ppi has 1000–1150 μm of cell size. Industrial in-line application of ceramic foam filters is as shown in Fig. 39. The LiMCA II inclusion concentration data (total detected inclusion counts > 15 μm in size) for a typical cast run of AA No. 1050 at a flow rate of 167 kg/min with a 15–50 ppi ceramic foam filter was demonstrated as shown in Fig. 40.^[39] And also it was

Fig. 38 Three- and two-dimensional images of the ceramic foam^[37]

Fig. 39 CFF filter box (From FOSECO)

revealed the mean filtration efficiency for the fine pore CFF (50 ppi) had increased to 76% from 69% for the coarser pore CFF (30 ppi). Cake filtration takes place on the surface of filter medium in the case of inclusion diameters which are of the same order of size or larger than the holes in the

Fig. 40 LiMCA II inclusion concentration data for 15–50 in ppi CFF^[39]

Fig. 41 Cross-section through a drained 50 ppi CFF (metal flow direction is from left to right), (a) and inclusion agglomerates found within a drained 50 ppi CFF, (b)^[39]

filter medium such as oxide film. Depth filtration was also observed within the foamed filter medium on its internal surface as shown in Fig. 41.^[38,39] On the other hand, Fig. 42 reveals the release of inclusions from ceramic foam filter (30 ppi) during casting, and such a release has occurred for no specific reasons.^[40] Although the filtration efficiency of ceramic foam filter depends on the operation condition such as filter cell size, metal flow rate and inclusions concentration before filtration, generally, 30 ppi ceramic foam filter can only be considered as a prefilter for critical products such as can body alloy.^[40]

Deep Bed Filtration-DBF An example of deep bed filtration apparatus (Alcoa 94 process) is as shown in Fig. 43.

It is strictly a packed bed tabular alumina filter. The size of the filter bed depends on metal flow rate. The life of such a filter is 5000t for unfluxed low-grade scrap, and up to 25,000t for prefluxed metal. The packed bed filter was improved to extend the life and remove hydrogen gas by diffused argon being passed countercurrently through the melt (Alcoa 181 process-U.S. Patents 2963558 and Alcoa 469 process-U.S. Patent 2863558). Deep bed filters exhibit inclusion release at start of cast and very stable filtration performance afterwards as shown in Fig. 44.^[40] Deep bed filters that are maintained in operation for several thousands of tons are much more stable due to their larger surface and volume of filtration. Nevertheless, as demonstrated in Fig. 44, deep bed filters present a release of

Fig. 42 Release of inclusions from CFF (30 ppi) during casting^[40]

Fig. 43 An example of deep bed filtration (Alcoa 94)^[25]

inclusions at start of casts for a short period of time during the increase of the metal flow rate from zero to the nominal casting flow rate.

Rigid Porous Media Tube Filter-RMF RMF is utilized in the form of the cartridge filter and it was the earliest applications of the bonded particle filter media (alumina, corundum or silicon carbide). The bonded particle filter structure consists of an aggregate of mineral grain bonded with a ceramic/glass composition resistant to molten aluminum. The microstructure of a bonded particle filter (Fig. 45) differs considerably from ceramic foams.^[41] The porosity of a BPF (Bonded particle filter) is related to a repetitive face centered close packed cubic structure, which yields a void space result 38–42%, roughly half that for a ceramic foam filter. RMF by TKR (Japan) has three grades of average pore diameter which are 760 μm (HAA), 450 μm (HC) and 340 μm (HE).^[42] Bonded particle tube cartridge filter is generally utilized as shown in Fig. 46.^[43] Filtration efficiency of RMF medium grade was studied by both theoretical and simulation method in comparison with those of DBF and CFF, and the result was as shown in Fig. 47.^[44] The investigation of the filtration efficiency of

MCF (Metaullics tube cartridge filter) revealed MCF was more effective than CFF of 30 ppi or 50 ppi.^[39]

REMOVAL OF ALKALI AND ALKALINE EARTH METALS FROM MOLTEN ALUMINUM

It is known that a couple of ppm of Na in Al-Mg alloy causes cracking during hot rolling. The removal of alkali metals such as Na and Li in molten aluminum alloy which is alloyed primary aluminum from electrolytic cell with alloying metal is generally implemented by furnace chlorine fluxing in the smelters. The chlorine fluxing in the holding furnace is also for the purpose of the removal of inclusions in the melt. The melt from the holding furnace is in-line treated by SNIF, GBF et al. before the casting at the cast station. The efficiency improvement of alkali removal by chlorine gas purging in the holding furnace of the

smelter-based casting system can be attained by the chemical engineering methods which increase the efficiency of chemical reaction between gas and liquid. The methods involve melt stirring, gas dispersion through the melt and fine gas bubbles dispersion into the melt.^[45–48] Stevens and Yu studied the reaction rate controlling mechanisms in the stirred tank reactor of Alcoa 622 unit (Fig. 48) in which a gaseous mixture of argon and chlorine was dispersed through the aluminum melt.^[45]

The rotor used in the reactor was a standard 305 mm diameter Alcoa 622 process rotor. The reactor contained approximately 998 kg of molten aluminum to which a known amount of calcium was added and which was maintained at a temperature of 732°C.

After examining a wide range of experimental batch reactor data, a conclusion was reached that two different reaction rate equations were required. Figure 49 shows some typical experimental data which illustrate this point.

Fig. 50 First order rate constant for calcium removal vs chlorine concentration^[46]

Fig. 51 Demonstration of the persistence of Ca removal from an alloy containing 1% Mg after the cessation of chlorine addition^[46]

When Ca concentration is greater than 0.006%, chlorine transport to the surface of the bubble controls the rate of reaction. Thus, reaction rate is independent of Ca concentration, and a zero order reaction is observed. However, when Ca concentration is less than or equal to 0.006%, the transport of calcium through the melt to the surface of the bubble controls the rate of reaction. A first order reaction is observed. Chlorine gas in N_2/Cl_2 mixtures is employed during furnace fluxing in amounts that exceed the theoretical requirements due to inefficiency of static lance fluxing and furnace geometry. Celik and Dautre^[46] investigated the effect of chlorine concentration on the rate of alkali/alkaline earth metals removal and tests were conducted in a 0.75 t furnace in which the removal rate at low levels of impurities (< 50 ppm) were determined as a function of gas flow rate and composition, metal composition (0%, 1% and 5% Mg) in the presence and absence of mechanical stirring, with and without bubble shear. This investigation revealed under all conditions examined, the removal rates followed first order rate kinetics indicating

that mass transfer (diffusion) in the liquid phase was the rate determining step. Figure 50 compares the first order rate constants for the removal of calcium from pure metal and from an alloy containing 1% magnesium. Calcium was chosen as representative of the alkali/alkaline earth metal because Ca is of concern in both the smelter and remelt systems and Ca is less volatile than Na or Li making the manipulation of Ca levels more reproducible. It is clear that the removal rates are higher from alloys containing Mg than pure Al. It is also apparent from the figure that the rate of Ca removal from the pure Al was independent of the chlorine concentration in the fluxing gas at all concentrations tested, whereas, in the presence of Mg a strong dependency upon the chlorine concentration was observed. Figure 51 provides an explanation for these observations.

During these experiments the melt was fluxed for a short period of time in order to establish the calcium removal rates following which the chlorine supply was interrupted and calcium levels determined at intervals for the remainder of the experiment. The discontinuities in the slopes occurred at the time at which the chlorine supply was turned off.

In the case of the pure Al, the rate constant for calcium removal fell immediately to a very low value. On the other hand in the 1% Mg-Al alloy the removal continued to take place. Celik et al. explained these effects are due to the formation of molten $MgCl_2$ (m.p. $714^\circ C$) droplets during fluxing which range in size upwards to $100 \mu m$. Being both small and relatively dense, these droplets can persist in the melt for some time before being eliminated by floating out or adsorption onto the furnace walls or dross layer. During their existence, these droplets can react substitutionally with Na, Li and Ca to form low melting point mixed chloride droplets which can be very difficult to remove from the melt, particularly during in-line chlorine fluxing. It is the reason why the in-line chlorine fluxing for alloys containing Mg by rotary injector should not be substituted for the furnace fluxing. Figure

Fig. 52 Demonstration of the increase in the rate of calcium removal by enhanced metal circulation and bubble dispersion in 5% Mg-Al alloy with 6% $Cl_2/94\% N_2$ ^[46]

Fig. 53 Na, Li, Ca removal from molten AA No. 3004 alloy by GBF with 5% Cl_2 /95% Ar

52 compares the rates of removal of Ca from 5% Mg-Al alloy under the following conditions: lance injection only, lance injection and mechanical stirring (remote from the point of gas injection) and gas injection via a rotary impeller.^[45] It should be noticed that the increase in the rate of impurity removal observed while using a rotary impeller to inject and disperse gas is due not only to the increase in the gas-liquid contact area but also to improved bulk metal circulation within the furnace. Figure 53 shows the experimental result of alkali and alkaline earth metals removal from molten Al-1% Mn-1% Mg by Ar + 5 vol% Cl_2 fluxing with GBF rotor (see the schematic diagram of GBF method in Fig. 17). Metallic sodium violently reacts with oxygen in the air and burns above the melting point (97.8°C). It may be due to the preferential oxidization of Na to form Na_2O_2 in gas at the surface of molten aluminum that we find the reduction of Na concentration after the simple

Fig. 54 Na removal from molten 5% Mg-Al alloy by GBF with Ar, 10% Cl_2 /90% Ar, 20% Cl_2 /80% Ar

melting operation. Kaestner et al.^[49] showed that by inert gas purging, about 92% of Na content was removed from the melt by evaporation from the surface and only 8% was carried out of the melt by the purge gas bubbles. Figure 54 shows the experimental result which reveals the difference of Na removal rate from molten Al-5% Mg alloy between Ar gas purging and Ar + Cl_2 gas purging all of which were implemented by GBF method. It is clear that Ar gas purging without Cl_2 is also effective to reduce Na concentration which is above 50 ppm in molten Al-5% Mg alloy to the concentration of a couple of decades ppm as well as Ar + Cl_2 gas purging. This result suggests Na removal by gas purging is almost by the oxidation and evaporation of Na from the melt surface while Na in the melt is above the approximated concentration of 50 ppm. Furthermore, the result of Fig. 54 reveals Ar + Cl_2 gas purging is necessary to reduce Na concentration to below 1 ppm.

THE IMPROVEMENT OF FURNACE FLUXING FROM THE ENVIRONMENTAL VIEW POINT

Although the installation of in-line facilities of molten metal processing has improved significantly molten metal quality, furnace fluxing remains to be necessary for higher aluminum quality because in-line processings remove impurities such as alkaline elements, hydrogen and inclusions in a proportional manner to the quality of inlet molten metal. The furnace fluxing consists usually of injecting chlorine gas or a gaseous mixture of nitrogen and chlorine through stationary lances. When chlorine is injected into molten aluminum, it reacts to form gaseous AlCl_3 . Upon exposure to the atmosphere, AlCl_3 reacts with moisture (H_2O gas) to form Al_2O_3 and HCl . The Al_2O_3 powder thus formed is responsible for the white “fog” observed during fluxing. In the presence of Mg, chlorine will react preferentially to form MgCl_2 which is liquid at the temperatures normally occurring during fluxing. At high temperatures, MgCl_2 can also hydrolyze to produce MgO and HCl .^[46] The time available for chlorine to react is limited by the residence time of the injected gas bubbles in the melt, thus free chlorine can also be present in the off-gases. Such a gaseous and particulate emissions from furnace fluxing of aluminum alloys must be reduced to meet ever more stringent environmental emission constraints. The emissions generated during fluxing were experimentally determined as a function of gas flow rate, gas and metal composition and degree of bubble dispersion.^[46] It was found that the reaction between Cl_2 and pure aluminum proceeds virtually to completion (AlCl_3 > 98% conversion) when the fluxing gas is introduced through a static lance 20 in beneath the melt surface. In the presence of magnesium, 50–90% conversion to MgCl_2 occurred, lowering the total amount of chlorine emitted (AlCl_3 + Cl_2). In Mg-containing alloys, the proportion of free chlorine emitted increased at higher chlorine concentrations, and the reason was considered to

be the rapid formation of a barrier layer of MgCl_2 which slowed the reaction between gaseous chlorine and Al or Mg. Increasing the gas/liquid interfacial area by such an injector as rotor type nozzle led to a substantial decrease in emissions from Mg-containing alloys due to increased efficiency of conversion of Cl_2 to MgCl_2 .

These results are summarized in Table 3. On the other hand, the effectiveness of chlorine in furnace fluxing on inclusion removal from Mg-free and Mg-containing alloys was also systematically evaluated and (apart from the generation of salt inclusions in Mg-containing alloys) no measurable differences in either the rate or extent of inclusion removal were observed. Furthermore, it was found that the prolonged cleansing effect of Cl_2 fluxing, even after the Cl_2 injection, in Al-Mg alloys occurs due to the secondary removal mechanism of residual chlorides in the furnace. Those results by Celik and Dautre suggest MgCl_2 salt may be a possible replacement for chlorine gas in furnace fluxing. Actually, salt addition and salt injection as alternatives to chlorine fluxing was studied in order to reduce gaseous and particulate emissions resulting from furnace fluxing of aluminum alloys.^[50]

For a long time, the addition of salts to the surface of molten aluminum bath has been available for the purpose of dross conditioning and furnace cleaning. In this case, the flux (salts mixture) usually contains chlorides, to provide a low melting point, fluorides to favor dross dewetting and metal coalescence and, exothermic agents such as sulfates, nitrates or carbonates. These fluxes on the bath surface cannot clean the bulk of the furnace, nor are they able to remove alkalis, owing to their chemistry. MgCl_2 based salts can achieve significant alkali reductions and it remove fluorinated compounds from the salt chemistry because MgCl_2 is also aggressive towards oxide films. In order to improve the treatment of the bulk of the melt, flux injectors into metal bath have been developed.^[51] Figure 55 shows an example of salt injection equipment. The feeder consists of a tank and a plate feeder. The feeder is fully automatic and gives a very accurate feeding rate. It is also equipped with an anti-clogging device. It is based on fluidized transport. However, to run such systems efficiently, further modifications to the flux chemistry are required.^[50] The melting point of the salt mixture, powder grain sizes and MgCl_2 hygroscopic tendencies must all be controlled to achieve safe, blockage-free injection. Once these parameters were under control, plant trials, performed in an 80 tonne smelter cast house furnace, produced encouraging

Fig. 55 An outline of a plate feeder such as the Feslente feeder^[51]

emission reduction level. However, metallurgical efficiencies were unsatisfactory, due to the lack of dispersal and stirring associated with lance injection.

In particular, dross remained wet. The result reveals that the injection of flux below the metal surface requires some sort of metal stirring in order to distribute the flux adequately in the furnace and achieve treatment of both the bulk of the metal bath and the dross layer. Table 4, 5 and 6 present results generated under full production conditions using a specially developed flux injection system based on the salt flux chemistry/injection/stirring principles (Rotary Flux Injection of industrial versions published in 1998^[52] was originated from here), in comparison with results of chlorine injection (AJS in Table 4 means Alcan Jet Stirrer).^[53] As shown in Table 4 and 5, injection and stirring of solid flux below the metal surface produces alkali removal rates and metal cleanliness levels equivalent to, or better than, those of standard lance chlorine fluxing. Emissions of HCl, Cl_2 and particulates by the use of salt injection and stirring were reduced by factors of 10–25, compared with standard chlorine fluxing as shown on Table 6. One aspect that should be paid particular attention was the possible entrainment of liquified salt residue into the product. These residues can have detrimental effects on some critical products. An analytical procedure of salt residue was developed based on a metallographic examination

of a solidified metal disk, and results revealed the solid flux injection technique accompanied by bath stirring resulted in entrained liquid chloride levels slightly higher than those of chlorine gas fluxing.

They also indicated inside in-line “degasser” units where the high specific energy available generates, in situ, chlorides in much larger quantities than those generated in the furnace. The finely divided droplets of liquid chlorides are easily entrained and are difficult to separate from the melt. Recently, a new type of flux which is more environmentally efficient has been developed (Y. Ohno of FOSECO, personal communication, 1998). The flux

(PROMAG) which consists of KCl and MgCl₂ is flaky crushed powder of fused salts mixture and it has low melting point of 480° C. PROMAG is introduced to the melt via an argon gas mixture and is mechanically stirred. In Europe, it has been used to effectively remove inclusions from recycled scrap used in the production of thin sheet and foil. Although it was demonstrated that salt injection and stirring method was possible to be an alternative with emission reductions to the use of chlorine gas fluxing, it is a fact that there remain several technological subjects to be solved.

Nanocomposites with Aluminum Matrix: Preparation and Properties

Jacopo Fiocchi, Riccardo Casati, and Maurizio Vedani

Politecnico di Milano, Milano, Italy

Abstract

Metal matrix nanocomposites are a novel class of materials, consisting of a metallic matrix reinforced by nanoparticles. They display interesting mechanical and functional properties, which can be carefully tailored and may be largely different than those of the base metal. Aluminum matrix nanocomposites have risen particular attention thanks to their low density and improved strength. Some issues in the production of nanocomposites are caused by the low wettability of nanoparticles; hence, innovative synthesis methods have been developed. In this work, the main production routes are reviewed; moreover, the strengthening mechanism acting in nanocomposites and the resulting mechanical properties are reported. Finally, the influence of reinforcement on precipitation processes in aluminum-based composites and some potential applications are described.

Keywords: Aging; Aluminum; Metal matrix nanocomposites; MMnC; Process.

INTRODUCTION

Metal matrix composites (MMCs) are well-known materials in which hard reinforcements, usually ceramic, are introduced into ductile metallic matrices in order to improve their behavior in functional and structural applications. The reinforcement may be present as fibers (mainly introduced to facilitate the material use at ultimate use temperature) or as discontinuous particles.^[1] Depending on the reinforcement, physical (for example, electrical and thermal conductivity, neutron absorption), mechanical (hardness, tensile strength, creep behavior), and tribological properties (wear resistance, friction coefficient) may be tailored over an extremely wide range.^[2] In recent years, research efforts have been aimed at reducing reinforcement size to the nanoscale in order to exploit interactions between particles and dislocations that, together with already known MMCs strengthening mechanisms, produce remarkable improvement in mechanical properties.^[3]

Reinforcement contribution to overall mechanical strength in metal matrix nanocomposites (MMnCs) is due to two different kinds of mechanisms: on the one hand, during loading, stresses are transferred from the matrix to nanoparticles; on the other hand, the reinforcement presence strongly changes the surrounding matrix properties by affecting dislocation density and motion. Different strengthening mechanisms may be identified in each class, namely, load bearing effect in the first one, Hall–Petch strengthening, Orowan effect, and coefficient of thermal expansion (CTE) mismatch and elastic modulus (EM)

mismatch in the second one.^[3] All these strengthening contributions, except the Orowan mechanism, are present in both micro- and nano-reinforced composites.^[4] The actual contribution of each mechanism may be described by some models and depends on nature, size, distribution, and volume fraction of the reinforcing particles.

During loading, stresses are transferred from the soft metal matrix to the hard particles. This can be described by the shear-lag model, originally proposed for short fibers by Cox^[5] and later modified by Nardone and Prewé.^[3] This model is based on the transfer of tensile stresses to particles by means of interfacial shear stresses. It is known that grain size plays a fundamental role in determining strength of metals: during slipping, dislocations pile up against grain boundaries. The number of dislocations in each pileup increases with increasing stress and grain size. These pileups induce in adjacent grains a stress concentration that grows if the number of dislocations in each pileup increases. Hence, as far as smaller grains contain a lower number of dislocations, a much larger stress is needed in fine-grained materials to allow dislocations to cross grain boundaries. The increase in strength may be computed by the Hall–Petch equation. In MMnCs, reinforcing particles act as pinning points retarding or stopping grain growth. Hence, grain size, described by the Zener's model, decreases if volume fraction increases and particle dimension decreases. On the other hand, the grain size reduction in nanocomposites is not caused by nanoparticles acting as heterogeneous nucleation sites as far as this happens only for particles in the order of micrometer.^[4] Moreover, it has been demonstrated that, when grains are smaller than

10 nm, they are not able to support the formation of pileups and strength decreases. For nanometric grains larger than 10 nm, an inversion in Hall–Petch relation is still possible and has been related to different possible causes. The models proposed to explain this behavior are based on dislocation motion, grain boundary diffusion, grain boundary shearing, and on the description of nanocrystalline metals as two-phase materials.^[6,7] Since reinforcement is usually ceramic, particles show thermal expansion coefficient and elastic moduli that largely differ from those of the metallic matrices, causing different expansion during cooling or heating and a different deformation under stress. The resulting mismatch is accommodated by geometrically necessary dislocations, which are concentrated at the particle–matrix interfaces and increase the material strength: if dislocation density increases, their own movement becomes more difficult. The overall strengthening of the two contributions can be estimated by Taylor equation.^[3]

Orowan strengthening is based on the resistance offered by hard particles to the movement of dislocations and is substantially similar to dispersion hardening induced by incoherent precipitates.^[8] To pass through a particle array, dislocations have to bow, thus consuming more energy because of their lengthening. When a critical bending angle is reached, dislocation lines may get closed forming loops around the particles.^[9] This mechanism is characteristic of nano-reinforced composites, but not of micro-reinforced ones, as far as microparticles are too large and widely spaced to act significantly in this way.^[4]

Thanks to their properties, MMnCs are considered promising materials for structural applications, which could make possible designing strong lightweight components, characterized by excellent mechanical performance even at high temperatures. However, as far as MMnCs are a very recent development, several theoretical and practical issues regarding their behavior and production still have to be overcome in order to obtain materials with a balanced set of mechanical properties (mainly toughness and strength). Processing techniques require further improvements to obtain satisfactory and reproducible results and to move on to an industrial-scale production; some physical aspects regarding strengthening mechanisms and aging behavior should be better understood.

TYPES OF METAL MATRICES AND REINFORCEMENTS

Many different metals, both in pure state and as alloys, have been used as matrices for MMnCs: the most common ones are aluminum, magnesium, titanium, and copper. Aluminum^[10–16] and magnesium^[17–19] have risen to researchers' attention because of their low density that allows producing lightweight composites, which are interesting materials in many demanding fields such as automotive and aerospace. Copper,^[20] because of its high

conductivity, and titanium^[21] have been widely studied as well. Research works have been concentrating on the use of pure metals for long time; however, recently higher attention has been devoted at employing commercial alloys. Different aluminum alloys have been employed in producing MMnCs: the most common ones are those belonging to 2xxx (Cu)^[11,16,22,23] and 7xxx (Mg) series,^[24] because of their high mechanical properties, and the ones in 6xxx (Si-Mg)^[25] series, which are suitable for casting.

Reinforcements improve mechanical properties of aluminum matrices and allow expanding their field of application. Several nano-sized oxides (Al_2O_3 , Y_2O_3),^[10,12,26,27] nitrides (Si_3N_4 , AlN),^[28] carbides (TiC , SiC),^[13,17,19,23,29–31] and borides (TiB_2)^[20] have been used as reinforcement. Some intermetallic compounds have also been employed (for example, NiAl, Al_3Ti). The possibility of using carbon allotropes, for example, carbon black,^[32] fullerenes,^[33] carbon nanotubes (both single and multiwall ones, usually named CNTs and MWCNTs, respectively),^[11,34] carbon nanohorns, and graphene,^[35,36] has been also studied.

The reinforcement/matrix coupling has to be carefully chosen in order to achieve the desired set of properties, which may be not limited to the mechanical ones. The production technique has to be compatible with the selected materials. For example, CNTs may be used to increase both strength and electrical conductivity, but their reaction with molten metal must be carefully considered in casting.

PRODUCTION TECHNIQUES

The main challenge in producing bulk MMnCs consists in ensuring a good dispersion of nanoparticles in the metal matrix. This issue is made difficult by low wettability and high surface area of particles that often lead to their agglomeration and inhomogeneous distribution. This is a strongly undesired scenario since it would make reinforcement ineffective in hindering dislocation motion, thus reducing the strengthening effect.^[26] Several synthesis routes have been developed to overcome this problem.

A simple classification of production processes is based on the physical state of matrices during processing (liquid, semisolid, or solid); methods belonging to these classes may be further divided between those in which the reinforcement is produced “in situ” during the synthesis itself and those in which nanoparticles are first produced “ex situ” and then embedded in the metal matrix to produce nanocomposites. The main methods are reviewed in the following section.

Liquid Processes

Traditional casting methods heavily suffer from aggregation of nanoparticles even though mechanical stirring is applied. Hence, several unconventional methods have been

Fig. 1 Schematic of the cavitation and streaming effect induced by ultrasonication in molten metals: (a) Formation and growth of bubbles, (b) collapsing of bubbles, and (c) breakup and re-dispersion of nanoparticle clusters^[17]

developed in order to overcome the problems caused by the high metal viscosity and poor nanoparticles wettability.

Ultrasonic Assisted Casting

This process aims at avoiding agglomeration of nanoparticles by introducing an ultrasound source in the molten metal bath: ultrasonic waves are able to locally generate transient cavitation and acoustic streaming. During negative pressure cycles, i.e., when ultrasonic waves induce expansion, microbubbles are generated that later collapse during the positive pressure cycles (Fig. 1). Bubbles implosion locally causes extremely high heating-cooling rates (10^9 K/s) and pressure gradients (1000 atm), thus breaking nanoparticles clusters.^[15] A secondary effect consists in improving the wettability of nanoparticles: the generated high pressure causes gas desorption from reinforcement surface, thus increasing surface energy to the value found in vacuum. The increasing of σ_{sv} turns out to reduce the contact angle between the molten metal and the solid particle, i.e., to improve wettability.^[37] In Ref. [15], a good dispersion of nanoparticles and a finer grain size was achieved by applying ultrasonication to the molten bath (Fig. 2), the Si-rich eutectic phase appeared to be better dispersed as well.

Spray Forming

Spray forming is a well-known technique, frequently used for coatings. In spray forming, a metal is melted, usually

by induction or plasma, and poured through a nozzle. The free-falling stream is broken into fine droplets by an annular array of gas jets. When droplets in the semisolid state are driven to the substrate by a gas jet, they stick to it creating the desired shape. Reinforcing particles may be introduced ex situ inside the molten bath or be formed in situ by reaction between metal droplets and a reactive gas. The high cooling rate on the substrate results in a fine microstructure characterized by homogeneous distribution of second phases.^[38] However, some problems may arise because of the high temperatures at which the process occurs. In Ref. [39,40], the authors described the formation of a 5 nm thick SiC layer at the interface between the aluminum matrix (an Al-Si alloy) and CNTs (Fig. 3). This, along with a nonoptimal distribution of reinforcement, caused a strong decrease in elongation to failure (EF) with respect to the base alloy (46%), even though a remarkable increase in EM (78%) was reported.

Disintegrated Melt Deposition

In this process, ex situ particles are introduced in a molten metal bath and mechanically stirred by an impeller. The molten slurry is poured, disintegrated by inert gas jets, and deposited. This technique differs from spray forming in employing higher superheat temperatures and lower impinging gas velocities. These features turn out to favor particles wettability and dispersion and to guarantee a higher microstructural homogeneity.^[41]

Fig. 3 Presence of silicon carbide layer (~5 nm) on CNT surface in plasma spray formed hypereutectic Al–Si composite reinforced with MWCNT^[39]

Selective Laser Melting

Selective laser melting (SLM) is an additive manufacturing technique, which allows producing complex-shape components directly from composite loose powders.^[42] Bulk structures are produced by selectively melting metallic or composite powders in a layer-by-layer approach. Gu et al.^[43] were able to tailor TiC reinforcement distribution inside the Al matrix by controlling laser energy. At low laser energy, the reinforcement morphology was characterized by inhomogeneous clusters; by increasing the input, an optimal ringlike distribution along aluminum grain boundaries was obtained (Fig. 4). This novel structure, if not coarsened, was useful in limiting matrix grain growth and improving load transfer between matrix and reinforcement. Improved tensile strength without elongation loss with respect to the base alloy was reported.

Semisolid Process

Rheocasting and semisolid casting are novel methods to produce MMnCs. Few works regarding these techniques can be found in literature, even though they have been widely applied to micro-reinforced composites. Particles are introduced in a molten metal bath under vigorous agitation or ultrasonication. The liquid is later poured into a steel injection sleeve. Slow cooling allows reaching 30% solid fraction before injection inside a preheated mold. The low viscosity of the metal mass allows avoiding turbulences that would entrap air causing oxidation. Aluminum-based composites reinforced by both alumina nanoparticles and CNTs have been successfully produced by rheocasting.^[44,45] De Cicco et al. obtained a refined globular microstructure thanks to nanoparticles acting as nucleating agents and obstacles for grain growth.

Fig. 4 High-magnification field emission scanning electron microscopy (FE-SEM) images showing dispersion morphologies of nanoscale TiC reinforcement in SLM-processed TiC/AlSi10Mg nanocomposites at different laser energy densities (E): (a) $E = 160 \text{ J mm}^{-3}$, (b) $E = 200 \text{ J mm}^{-3}$, (c) $E = 240 \text{ J mm}^{-3}$, and (d) $E = 280 \text{ J mm}^{-3}$ ^[43]

Solid Processes

The powder metallurgy route has been widely used to produce MMnCs through different processes, such as hot pressing (HP), extrusion, rolling, and equal channel angular pressing (ECAP). Metallic micro-sized powders are usually mixed with nanoscale ceramic particles and later consolidated. In the following sections, mechanical alloying will be first described because of its importance in mixing and modifying powders; later the fundamentals of sintering and the main processes will be analyzed.

Mechanical Alloying

Mechanical alloying is a technique that allows producing uniform materials starting from different kinds of powders, first developed in the late 1960s at INCO company.^[46] It is used for a variety of purposes; such as mixing powders, changing their shape, dimension and structure, producing oxide dispersion strengthened metals and composites, activate powders and induce chemical reactions. During the process, particles are subjected to heavy plastic deformation that causes flattening and increasing in work hardening. When a critical value is attained, powders fracture because of fatigue or by fragmentation of brittle flakes. The new surfaces easily weld together causing the characteristic layered structure. After sometime, equilibrium is reached between the competing processes, and powders dimensions stabilize. If brittle particles are present too, they get entrapped among ductile layers (Fig. 5).

Different milling facilities exist, such as tumbler mills, attrition mills, shaker mills, vibratory mills, and planetary mills. The last one is very common for producing MMnCs: it is based on a main and a planetary disc rotating in opposite directions and supporting the vials containing powders and milling balls. The centrifugal forces alternately acting in different directions on the balls induce

friction and impact effects on powder. Many parameters may be set to control the process and modify the properties of nanocomposite powders: milling time, balls to powder ratio (equilibrium phases are obtained in hard conditions), process control agent (PCA, reduces cold welding by absorbing onto powder surfaces), rotation speeds, and milling atmosphere (gases may induce chemical reactions). Reinforcement may be present both as ex situ, if previously prepared particles are added and mixed, and in situ, if it is produced during milling. This may happen thanks to chemical reactions between metallic powder and processing gas or by breaking into fragments the powder surface oxide layer.^[47] The high energy provided by milling is able to induce several types of reactions, which produce hard phases: for example, aluminum carbides may be formed by decomposition of the PCA, oxides and nitrides are generated by interaction with milling atmosphere,^[48,49] or by displacement reactions between aluminum and different reactants (for example, ZnO.^[50] Additionally, the nanoparticles accelerate the milling process and refine the grain structure^[51] by locally inducing heavy plastic deformation of metal powder. This improves the metal particles fracture and welding process and results in an overall acceleration of milling kinetics. Fogagnolo et al. reported a 50% milling time reduction by the addition of 5% AlN to aluminum matrix with respect to the processing of the unreinforced powders.^[52]

Sintering

Sintering is a thermomechanical process that bonds together loose particles into a solid and coherent structure.^[53] The main driving force acting during the process is surface energy reduction, which may be aided by an applied pressure. During the process, the material may be fully solid or partially liquid. In the first case, it is carried out at a temperature slightly higher than one half

Fig. 5 The various stages of a ductile–brittle system during mechanical alloying^[52]

of the melting temperature, and the main mechanism is solid-state diffusion. Liquid-phase sintering exploits the presence of some molten material to accelerate the process. Traditional solid-state sintering occurs in different stages:

- Initial stage: when particles touch each other, a neck starts growing in the contact point. Many mechanisms, including evaporation–condensation, volume diffusion, surface diffusion, grain boundary diffusion, plastic and viscous flow, help in moving atoms to the neck region. Densification occurs only if atoms move from particle interior toward the neck region. The main driving force is the reduction of surface energy.
- Intermediate stage: it is characterized by pore rounding, densification, and grain growth. Pores become nearly cylindrical and form a fully interconnected network (open porosity). The closure of pores is based on diffusion of vacancies from the pore surface to the bulk of powders. The acting driving force is still surface energy reduction.
- Final stage: it is a slow process during which densification and grain growth cause breakup of cylindrical pores into discrete ones (closed porosity). Grain boundary migration during grain growth causes pore insulation inside grains and possible gas trapping.

It has always been a problem, even for micro-reinforced composites, to achieve a uniform distribution of particles inside the metal matrix by powder metallurgy methods. In Ref. [54], the authors derived a model predicting the minimum size of reinforcement, able to guarantee a good dispersion, as function of matrix powder size, reduction ratio of deformation process, and volume fraction of reinforcement. By plotting interparticle spacing versus size of reinforcement (Fig. 6), it is clear that achieving a good dispersion becomes more and more challenging as reinforcing particles approach the nanometric range.

Hot Pressing and Hot Isostatic Pressing

In HP, sintering is achieved by simultaneously heating and pressing powders. Heat is provided by using an induction coil or electrical resistances; uniaxial pressure is applied by means of a plunger, which pushes the upper part of the sample inside a die. In hot isostatic pressing, the required pressure is applied not uniaxially but hydrostatically: a can filled with powder is placed in a heated vessel, later pressurized by introducing an inert gas. This allows obtaining uniform pressure on the whole sample and very low strain rates. This process turns out to be very useful in producing complex shapes that would be impossible to obtain by HP. The process has been frequently used to produce MMnCs but may require some adjustments; for example, Wan-li^[55] obtained good results by lowering the processing temperature and increasing the applied pressure (723 K and

Fig. 6 Effect of reinforcement size and volume fraction on interparticle spacing of reinforcement^[54]

100 MPa against 873 K and 10 MPa): this allowed to avoid agglomeration of nanoparticles. The optimal temperature allowed to avoid interfacial reaction between aluminum and SiC particles, whereas the increased pressure was useful in ensuring full compaction.

Powder Rolling

During roll compaction, loose powders are continuously fed to a set of rolls, which produce a green sheet. The compacted strip is then sintered in a furnace and eventually cold rolled to obtain the desired properties and shape.^[56]

An alternative route, which has also been used to produce composites, is based on direct compaction of powders by hot rolling: powders are cold pressed in a sealed can and then rolled at elevated temperature to achieve sintering.^[11] Recently, SiC-reinforced aluminum nanocomposites were successfully compacted by rolling by the authors of the present work.^[57,58] The process was found to be simple, easily reproducible, and did not require any specific equipment. The obtained nanocomposites exhibited improved strength and retained a fully satisfactory ductility.

Hot Extrusion

Extrusion is a broadly used forming method that can be successfully adapted to powder consolidation and production of MMnCs.^[12,25,26,47] Powders are cold pressed in a sealed can or directly poured into a die, and then extrusion is performed by pressing the sample and forcing it through a lower diameter outlet. The high temperature, typically two-thirds of the absolute melting temperature, and pressure induce powder sintering. The advantage over traditional sintering methods lies in the ability of extrusion to refine grain structure by recrystallization thanks to the high strain rates, which are induced during the process.^[56]

Typically, a fine texture with elongated grains lying parallel to extrusion direction is obtained. A further advantage lies in breaking the superficial oxide layer of powders because of shearing: direct contact between metallic surfaces is ensured, and sintering is enhanced. In Ref. [59], extrusion revealed to be able to consolidate powder and to align CNTs along the extrusion direction (Fig. 7) giving rise to strongly anisotropic mechanical properties. The authors reported that during tensile tests, failure was caused by nucleation of micro-voids at matrix–CNTs interface; however, no such voids were recognized after consolidation (Fig. 7), thus confirming the effectiveness of the compaction process.

Equal Channel Angular Pressing

ECAP is a well-known technique that allows inducing severe plastic deformation (SPD) in the processed sample. SPD causes a continuous recrystallization process thanks to the extremely high amount of cold work induced in the metal and is thus able to produce ultrafine-grained materials. Another important SPD

laboratory technique is high-pressure torsion straining, which, as ECAP does too, exploits hydrostatic compression to avoid sample cracking. ECAP processing consists of pushing by means of a plunger a sample through a die characterized by two intersecting channels with the same diameter, which are responsible for inducing extremely high shear strain in the sample without changing its section. Usually the same billet is subjected to more than one pass to achieve homogeneous grain refinement. Passes are performed according to different routes (the sample is rotated in different ways between two steps), which are tuned in order to achieve a satisfactory final microstructures.^[60]

It is reported in literature that ECAP is arising as a promising method for producing MMnCs by powder consolidation.^[12,27,61,62] The mechanisms involved in powder consolidation by ECAP are radically different than the ones exploited by traditional sintering.^[61] Instead of relying on solid-state diffusion, SPD induces heavy plastic deformation that breaks the superficial brittle oxide layer of powders exposing fresh metal surfaces that spontaneously bond together. The material flow associated to plastic deformation completely fills voids between particles, resulting in full densification at the first step. More passes may be performed in order to obtain a finer microstructure. In Ref. [63] pure aluminum and Al_2O_3 nanoparticles were subjected to ball milling and then consolidated by ECAP: one step was enough to obtain full dense material, but nanoparticles were still agglomerated in clusters (Fig. 8a). After 12 passes, a uniform dispersion was achieved (Fig. 8b). High temperatures are not requested to achieve powder consolidation by ECAP; hence, this process appears to be particularly suitable for producing MMnCs reinforced by particles, which are unstable with respect to temperature (for example, cryomilled particles).^[48]

(b) Alignment of CNTs and lack of voids surrounding CNTs in a sample not subjected to tensile testing^[59]

MECHANICAL PROPERTIES OF ALUMINUM-BASED MMnCs

The mechanical behavior of aluminum matrix nanocomposites is strongly improved by the presence of reinforcement with respect to the base material. In Fig. 9, two Ashby diagrams depicting EM and tensile strength of engineering materials versus density are reported.^[64] It is evident that MMnCs exhibit improved modulus and strength with respect to pure metals and alloys. Table 1 reports a summary of the mechanical properties of MMnCs measured in some literature works: it may be noted that the presence of reinforcement generally improves the yield strength (YS) and ultimate tensile strength (UTS). On the other hand, no monotonous trend is visible as far as EF is concerned: EF is often improved by reinforcement in composites produced by liquid processes, whereas it is generally depressed when a powder metallurgy route is followed.

YS = Yield stress; UTS = Ultimate tensile stress; EF = Elongation to failure.

Elshalakany et al.^[45] attributed the improved performances of a nanocomposite produced by rheocasting and squeeze casting to the activation of a cross-slip mode in dislocation motion induced by the presence of MWCNTs. On the contrary, in composites produced by plastic deformation the high amount of defects (nanoparticles, dislocation tangles, and grain boundaries) often induces a strong reduction in ductility.^[58]

The EM of nanocomposites is also usually improved with respect to one of the base materials. The increment may be described according to various models, depending on nature, shape, and distribution of nanoparticles, which however often overestimate the resulting properties.^[36] Outstanding improvements in EM values were obtained by adding CNTs to aluminum thanks to the very high modulus that characterizes CNTs (350–970 GPa): for example, Laha et al.^[40] were able to increase the modulus of an AlSi alloy produced by plasma spray forming from 67.5 GPa to 120.4 GPa thanks to the addition of 10% SiC nanoparticles. The introduction of SiC nanoparticles into aluminum matrices gives similar results: Fig. 10^[65] shows the evolution of the EM as function of SiC concentration in an Al–SiC composite produced by ball milling and plasma-activated sintering.

The presence of the reinforcing phase is also beneficial to the damping properties of aluminum alloys: besides the individual damping capacities of each constituent, the interface between matrix and reinforcement contributes to damping through sliding friction mechanism and by generating a high concentration of dislocations, whose internal friction upon moving dissipates energy during vibration.^[66] For example in Ref. [26], the damping ability of aluminum produced by extrusion was measured by the $\tan\delta$ parameter and resulted strongly increased by the presence of both in situ and ex situ alumina nanoparticles.

PHYSICAL METALLURGY OF ALUMINUM-BASED MMnCs

Heat-treatable aluminum alloys are widely used to produce MMnC, but, at the present time, little work has been done to thoroughly understand and exploit the aging mechanisms, which allow precipitation strengthening. By solution treating and quenching an aluminum alloy, a supersaturated solid solution (SSSS) is obtained: solute atoms are dissolved in the matrix during holding at high temperature and, because of fast cooling, do not have enough time and energy to diffuse and form different phases. As far as aluminum is concerned, the SSSS phase has a face-centered cubic crystalline structure and is called α_{ss} . During natural or artificial aging, atomic diffusion is enhanced by the temperature allowing metastable and stable phases to precipitate, showing different compositions and crystalline structures depending on the present alloying elements. This procedure allows to exploit the precipitation hardening mechanisms.

It is widely reported in literature that reinforcing microparticles heavily affects precipitation kinetics in heat-treatable aluminum-based MMCs. These effects arise from different causes:^[67]

1. The CTE mismatch between particles and matrix causes thermal stresses and hence formation of dislocations forests. These thermally induced dislocations influence precipitation mechanisms by acting as preferential diffusion paths for solute atoms, annihilating excess vacancies and providing heterogeneous nucleation sites.
2. Particle–matrix interfaces act as sinks for vacancies and as heterogeneous nucleation sites.
3. There may be chemical reactions between reinforcement and matrix, causing solute depletion or enrichment.

Fig. 10 Evolution of EM as function of reinforcement fraction in a Al–SiC nanocomposite^[65]

These effects turn out to modify the aging behavior in the following ways:

1. The quench sensitivity of MMCs is strongly enhanced.^[68]
2. Aging kinetics are accelerated in MMCs, hence peak hardness conditions are reached for shorter times in both natural and artificial aging.^[13,68–72]
3. Precipitation sequences may be changed, even though not all precipitates are affected. For example, Guinier–Preston (GP) zone formation is almost suppressed because of the lower presence of quenched vacancies.^[70,73]

The introduction of external particles into the matrix does not substantially change the usual precipitation sequence. However, reinforcement influences in different ways the formation and dissolution of each phase, according to the previously reported mechanisms. Some examples related to Al–Cu–Mg alloys are here reported. It is well known that GP zone precipitation mechanism is based on vacancy-driven diffusion. Hence, the annihilation of vacancies caused by dislocations arising at particle–matrix interface during cooling turns out to reduce the volume fraction of GP zones or even to suppress them.^[13,67,70,72,74,75] On the contrary, precipitation of θ' and S' is believed to be accelerated and to require lower energy in composites thanks to the higher density of dislocations that aid pipe diffusion and act as heterogeneous nucleation sites.^[16,69,74] According to Papazian and Adler, θ' precipitation is accelerated to a higher extent than S' one.^[13,76]

Little effort seems to have been spent in understanding how aging behavior changes if reinforcement is reduced to the nanoscale and whether the previously reported mechanisms are still valid or not. Choi and coworkers^[11] reported a MWCNT-reinforced 2024 alloy to reach peak hardness in 4 h, whereas the maximum hardness of the base alloy is obtained after an 18 h long aging. A similar result was achieved by Geng et al.^[23] who studied a $\text{SiC}_w + \text{SiC}_p$ -reinforced Al2024 (4 h to peak hardness for the composite, 12 h for the base material). In Ref. [23], the authors also recognized nanoparticles to affect strengthening far more deeply than micro-sized whiskers. Both articles reported that composites achieved a largely higher hardness in peak-aged conditions and that hardness displayed a faster but slighter decay toward overaging. Lin recognizes as causes of the different behavior the higher dislocation density and lower vacancy concentration in the composite, whereas Choi mainly looks at dislocations and MWCNTs as diffusion pathways. Casati et al.^[58] described accelerated aging kinetics and lower hardening upon aging in an Al2618 alloy reinforced by SiC and magnesium oxide nanoparticles: this behavior was attributed to the abundance of dislocations and to the solid solubility extension induced by ball milling. On the other hand, Saheb^[77] and coworkers found completely opposite results by studying CNT-reinforced Al6061: they

reported lower hardness values and longer peak times for composites than for the base alloy and attributed this behavior to the negative CTE of CNTs, low amount of vacancies and pores caused by CNT agglomeration.

APPLICATIONS OF MMnCs

Currently, the high cost of nano-sized reinforcement and the processing issues still limit the possibilities of employing MMnCs on a large scale. However, looking at recent advancements, it is reasonable to state that their use might become convenient in some demanding niche fields. MMnCs exhibit outstanding mechanical properties, which represent a huge advancement with respect to the characteristics shown by micro-reinforced composites. Hence, nanocomposites might replace microcomposites in some industrial applications.

Potential uses of MMnCs are anti-wear coatings, aerospace and automotive structures, electronic devices, and catalysts.^[78] For example, structural parts in aircrafts, space vehicles, or racing cars would be improved by the low density and high resistance of aluminum nanocomposites.^[79,80] An important research program, which involves both academic and industrial institutions, has been established by the European community. The ExoMet project^[81] aims at developing new casting techniques to spread the use of light metals nanocomposites. Improved nanocomposites would allow a better design of aircrafts thanks to redistribution of weights. Moreover, higher conductivity and strength can be achieved by producing wires and cables made of pure metals (for example, Cu and Al) reinforced by carbon allotropes. The European Space Agency is also particularly interested in possible weight savings which would allow the transport into space of higher payloads at a lower price.

CONCLUSION

Aluminum matrix nanocomposites have gained particular attention thanks to their low density and improved strength. Some issues in the production of nanocomposites are caused by the low wettability of nanoparticles; hence, innovative synthesis methods, based either on liquid process or solid-state sintering, have been developed. Ultrasonic assisted casting and SLM are promising liquid–metallurgy routes; as far as powder metallurgy is concerned, mechanical milling, followed by consolidation, by traditional sintering (HP, extrusion), or by SPD have risen as well-established techniques. The possibility of achieving a further improvement in mechanical properties by heat-treating aluminum-based MMnCs is still at a starting point and needs further investigation, also in a theoretical perspective.

Currently, the high cost of MMnCs and the complexity of production routes still limit the possibilities of

employing aluminum matrix nanocomposites on a large scale. However, looking at recent advancements, it is reasonable to state that their use will soon become convenient in many demanding fields.

Abstract

An overview of recent developments in the synthesis of aluminum nanoparticles (Al NPs) and their applications in the field of energetic materials is presented. Various methods of preparing the Al NPs of different sizes including physical (laser ablation) and chemical methods are highlighted. Some of the results obtained by our group on the passivation of the Al NPs are highlighted. The laser ablation in liquids technique with ultrashort (picosecond and femtosecond) laser pulses is a green technique for preparing Al NPs devoid of any precursors, whereas the chemicals method yields passivated Al NPs. Among the various applications of the Al NPs, energetic applications are discussed in detail. This article is concluded by emphasizing the prospects of Al NPs in various energetic applications and the future of different techniques to synthesize them.

Keywords: Aluminum nanoparticles; Burn rate; Chemical synthesis; Combustion; Nanoenergetic materials.

INTRODUCTION

Aluminum (Al) is a p-block, group 13, period 3 element that finds a variety of applications in automobiles and aircrafts, along with potential as an energetic fuel ingredient in rocket propellants. The large specific surface area and energy density of Al particles (both nano-sized and micro-sized), when coupled with oxidative species, make them unique combustible additives in propellant formulations. Many solid-, liquid-, and gas-phase techniques are available for synthesizing Al NPs. However, synthesis of high-purity Al nanopowders is a challenging task owing to their rapid oxidation possibility. Synthesis of small-sized Al NPs is achievable, but they are highly susceptible to excessive oxidation. Typically, the thickness of an oxide coating on an aluminum particle ranges from 1.7 to 6.0 nm, irrespective of the size of the particle.^[1] This adversely affects the actual or active Al content in the sample in an inverse manner. Hence, compared to size reduction, modification of Al NPs through passivation of the surface against the formation of an oxide surface layer is a more challenging task.

Several recent studies have shown that the size, morphology, stability, and properties (chemical and physical) of the metal nanoparticles (NPs) are strongly influenced by the experimental conditions, the kinetics of the interaction

of metal ions with reducing agents, and the adsorption processes of a stabilizing agent with metal NPs. Consequently, the design of synthesis methods in which the size, morphology, stability, and properties are controlled has become more demanding than just size control alone.^[2] The techniques for synthesizing Al NPs are usually based on solid-, liquid-, and gas-phase processes. The solid-phase techniques include mechanical ball milling and mechano-chemical process; the liquid-phase techniques include laser ablation, exploding wire, solution reduction, and decomposition process, whereas the gas-phase techniques include gas evaporation, exploding wire, and laser ablation process.^[1] In this article, apart from the applications of Al NPs mainly as an energetic combustion fuel, some of the chemical and physical methods developed by our group have been discussed in detail.

SYNTHESIS OF AL NPS

There are a number of methods reported in literature and available for the synthesis of Al NPs.^[3–31] Some of the recent methods developed in our laboratory to produce Al NPs are found to be very useful in producing surface-passivated Al powders. Our work mainly focuses on the solution-phase chemical synthesis as well as nanosecond/

femtosecond-based laser ablation. Some of the advantages of these methods and results are elaborated further.

Chemical Methods

The solution-phase synthetic techniques are attractive for the commercial production of Al nanopowder because of the inherent safety of handling the pyrophoric powder in liquid medium. These methods have an additional advantage of the ability to readily functionalize the particle surface. Although physical methods are established to produce Al NPs, only few reports are on the solution-phase chemical synthesis.^[32–34] The first reported method involved the reduction of AlCl_3 by lithium aluminum hydride (LiAlH_4) in 1,3,5-trimethylbenzene at 164°C . The second reaction involved the thermal decomposition of $\text{H}_3\text{Al}\cdot\text{NMe}_2\text{Et}$ at temperatures ranging from 50°C to 165°C in the presence of varying amounts of a titanium isopropoxide catalyst and tetramethylethylenediamine in 1,3,5-trimethylbenzene, xylene, or toluene as solvent. The thermal decomposition of $\text{H}_3\text{Al}\cdot\text{NMe}_2\text{Et}$ had a better control over particle sizes that ranged from 44 to 197 nm depending upon catalyst concentration. The Al NPs synthesized by this method are reported to suffer facile grain growth, which was ascribed to their chemical purity.

The major concern regarding starting materials used in the synthesis is their sensitivity to moisture. Also, it is interesting to establish a synthetic method, wherein purification of NPs is easy. In another alternative synthetic procedure,^[35] aluminum acetylacetonate [$\text{Al}(\text{acac})_3$] was used as one of the precursor materials (Scheme 1). $\text{Al}(\text{acac})_3$ precursor was primarily selected due to its solubility in mesitylene, which was required for a clean reaction. In a typical procedure, $\text{Al}(\text{acac})_3$ was reacted with LiAlH_4 at 165°C in mesitylene to obtain Al NPs. This procedure yields side products soluble in organic solvent that made easy purification of Al NPs. The side products were removed by repeated washing with dry, ice cold methanol, and the reaction mixture was filtered to yield gray-colored Al NPs. It was expected that the LiAlH_4 should transfer the hydride ions to $\text{Al}(\text{acac})_3$ forming aluminum hydride. Since the aluminum hydride was unstable over 160°C , the reaction proceeds via decomposition of aluminum hydride, followed by possible evolution of hydrogen gas.

Scheme 1

The formation of an unknown form of organic residue from the decomposition of acetylacetonate ligand was also observed from the reaction of $\text{Al}(\text{acac})_3$ with LiAlH_4 . This carbonaceous residue was found to be responsible for the stability of Al NPs. Similar formation of an unknown carbonaceous mass was observed during the synthesis of PtNi intermetallic NPs by Leonard et al. in 2011.^[36] The Raman spectrum of these Al NPs showed two peaks at

1350 and 1598 cm^{-1} , indicating the presence of some form of graphitic lattice.^[37] A large number of reactions in both organic and inorganic chemistries are known wherein LiAlH_4 was used as a reducing agent. Mechanism of this reduction/hydrogenation is well established in organic synthesis.^[38] However, the product from the reaction involving LiAlH_4 in inorganic synthesis was dictated by various factors including the nature of substrate.^[32,39–40] For example, the reaction between LiAlH_4 and AlCl_3 yielded Al NPs via aluminum hydride intermediate,^[32,41] which subsequently decomposed yielding Al NPs. In this reaction, Al from both the compounds yielded Al NPs. However, in an interesting reaction (Scheme 2), phase-pure Al NPs were obtained from the reaction of SiCl_4 with LiAlH_4 in toluene on exposure to ultrasound (sonication), while Si was leaving as hydrosilanes ($\text{H}_x\text{SiCl}_{4-x}$).^[42] The formation of hydrosilanes in this reaction is well documented in the literature.^[43–46] The mechanism of formation involves the reduction of LiAlH_4 by SiCl_4 yielding silanes, LiCl and AlH_3 . The formation of alane (AlH_3) from LiAlH_4 in reactions with AlCl_3 and other metal chlorides is also well documented.^[47] It is known that^[48–50] AlH_3 can be decomposed to yield Al and H_2 at a temperature range of 60°C – 200°C . Similarly, the alane formed in this reaction subsequently decomposed to form Al NPs under sonication.

Scheme 2

Polymer-Coated Al NPs

The production of Al NPs in larger quantities remains challenging because of its oxophilicity and the tendency of growing to form larger particles at the expense of smaller particles. In propellant science and technology, oxide formation on the surface of the Al NPs prior to combustion and quick agglomeration while burning are the two major problems^[51–53] focused by the researchers. Recent results^[54] showed that the protected Al NPs have an increased stability to oxidation in air and water during storage. Therefore, many efforts are devoted to the synthesis of Al NPs, which are protected by coatings or organic surface passivation under ambient conditions. Treatment of the Al nanopowders with oxygen at a low pressure (e.g., 0.01% of the total pressure) results in the formation of protective oxide coatings. These layers effectively stop further oxidation of NPs during their handling and storage. Passivation is usually achieved as a separate processing step, in which the chamber filled by inert gas for the production of Al powder is evacuated and refilled with an oxidizing gas mixture. These passivated Al particles contain 60%–92% Al depending upon the crystallite size.

Other approaches have also been considered in which the powder is either coated with another metal^[55] or passivated

by perfluorinated and non-fluorinated alcohols, acids, and 5-(hexadecyloxy)isophthalic acid^[56–58] or by epoxides.^[59,60] Bunker et al. reported^[61] a method in which Al NPs were synthesized inside the cavities of a perfluorinated ionomer membrane which could also act as an oxidizer. As an alternative method to address the problem of surface oxidation and also to take advantage of compatibility of polymers with energetic composition, the Al NPs are synthesized and stabilized inside polymer matrices.^[32,35,41] To produce the polymer-coated Al NPs, the compound AlCl_3 ^[32] or $\text{Al}(\text{acac})_3$ ^[35] or SiCl_4 ^[41] was reduced by LiAlH_4 in the presence of polymers under appropriate reaction conditions. The weight of polymer to obtain a particular Al:polymer weight ratio was decided assuming 100% theoretical yield of Al as per the stoichiometry of reaction. Using these methods, Al coated by either PMMA or poly(vinylpyrrolidone) (PVP) was obtained in good yields. The X-ray powder diffractogram of Al-polymer nanocomposite (data presented in Fig. 1) matched very well with crystalline Al data, and no aluminum oxide peaks were observed. The broad peak at a low angle region ($2\theta = 20^\circ\text{--}30^\circ$) was mainly because of the amorphous nature of polymer matrix.^[62] Field emission scanning electron microscopic (FESEM) investigations of the composites revealed the presence of nano Al particles of various shapes and sizes ranging from 15 to 300 nm.

²⁷Al MAS NMR as a Tool to Check the Purity

In recent years,^[63–65] high-resolution solid-state ²⁷Al NMR spectroscopy with magic angle spin (MAS) has evolved to be a potential tool to study the state of Al. It was recognized that the chemical shifts correlate with Al coordination number for both the organo aluminum compounds and the inorganic compounds of Al.^[63] For example, ²⁷Al signal of aluminum with six-coordinate, five-coordinate, and four-coordinate oxygen environments appeared from –10 to 15 ppm, 25 to 35 ppm, and 65 to 85 ppm respectively, whereas that of aluminum metal appeared at 1640 ppm.^[62,64] The solid-state ²⁷Al NMR with MAS spectra obtained for the freshly prepared Al-PVP and Al-PMMA samples

Fig. 2 ²⁷Al MAS NMR spectra of (a) AlCl_3 and (b) Al-PVP composite

depicted a strong signal at 1645.5 ppm (Fig. 2). A weak signal in the spectrum near 14 ppm was due to unreacted AlCl_3 . The absence of any signal corresponding to other forms of aluminum essentially reveals the purity of Al/polymer composites. Hence, ²⁷Al NMR with MAS could be considered as a useful method to study the purity of Al NPs. The ²⁷Al NMR spectrum of AlCl_3 that was used as starting material in synthesis is also shown in Fig. 2 for comparison.

Stabilization of NPs

The Fourier-transform infrared spectroscopic spectra of the PVP and PMMA containing Al NPs in their matrices were compared with those of the pure PVP and PMMA, respectively. The carbonyl stretching frequency of pyrrolidone in the PVP and that of the ester group in PMMA which appeared at 1600 cm^{-1} was unaltered after the reaction. The general observation was that PVP would coordinate with metal atoms through polyvinyl skeleton, C–N and C=O polar groups. In the vibrational absorption spectrum of pure PVP, the wave numbers 1665 and 1070 cm^{-1} were assigned to the C=O and C–N bond. In our Al-PVP composite, the peak at 1665 cm^{-1} was shifted to 1620 cm^{-1} and C–N bond vibrations at 1070 cm^{-1} in PVP shifted to 923 cm^{-1} as a result of bond weakening because of the partial donation of lone pair of electrons revealing a weak coordinative chemical bonding at the interfaces of Al and polymer. Thus, the lone-pair electrons of oxygen and nitrogen atoms in PVP involved coordinate bonding with atoms on the surface of Al NPs. This shows that the lone pair of electrons present in the oxygen and nitrogen atoms of the polymers are responsible for stabilization of NPs. These electrons appear to be coordinating with atoms on the surface of the Al NPs leaving aluminum atoms inside the bulk unaffected. Since the

aluminum atoms on the surface of the Al NPs are bound by coordination bonds with oxygens in PMMA and oxygens and nitrogens from the polymer chains, the particle agglomeration is hindered in the embedded NPs. Similar phenomenon of stabilization of metal NPs by lone pair of electrons present in the nitrogen atoms of poly(methylphenylphosphazene) and PVP has been established in gold,^[66] silver,^[67] and copper.^[68]

Thermogravimetric Analysis

Temperature region of oxidation of Al NPs embedded in polymer matrices was examined by thermogravimetric analysis (TGA), data of which are presented in Fig. 3. The thermogram recorded at a heating rate $50^{\circ}\text{C min}^{-1}$ depicted the weight loss up to 510°C associated with polymer decomposition which would leave Al exposed for oxidation. Consequently, after removal of polymer by decomposition, a gain in weight was observed up to 1275°C ,

Fig. 3 TG-DTG curve revealing the regions of PVP decomposition and major amount of Al oxidation regions
Source: Reproduced with permission from Gottapu, S.; Muralidharan, K. *New J. Chem.* **2015**, 39, 5203–5207. Copyright Royal Society of Chemistry.^[42]

which can be attributed to the oxidation. From this weight gain, the active Al content is calculated from the TGA curve following the procedure reported previously.^[18] The unaccounted mass could probably be attributed to (1) the formation of amorphous alumina (undetectable quantity in PXRD) in the synthesis, (2) leftover carbonaceous mass from burnt PVP in TGA, and (3) inherent error in active Al calculation because the TG temperature range of analysis did not reach the saturation point of Al oxidation.^[69]

The entire Al oxidation region above 510°C showed two distinct derivative thermogravimetric (DTG) peaks at 636.5°C and 968°C with 8.2% and 47.83% weight gains, respectively. A similar two-step oxidation was reported previously.^[70] The PXRD pattern of the residue obtained after TGA confirmed the growth of alumina phases. The Al oxidation process was initiated by available oxygen from PVP degradation and then ensued by surrounding air because of ineffective protection by purge gas (argon and nitrogen) at high TGA furnace temperature. This was evident from the fact that the second stage of oxidation was accelerated when the nitrogen purge gas (Fig. 4 data) changed to oxygen. Similar oxidation of Al in Ar/ N_2 environment was reported earlier. This explains the protection of embedded Al NPs by PVP from any significant oxidation below degradation, but after PVP removal, the oxidation of exposed Al NPs was ensued in the heating environment of Thermogravimetric Analyzer–Differential Thermal Analyzer (TGA–DTA) instrument. Progressive air oxidation of polymer-coated Al NPs was monitored by PXRD with frequent time intervals over 1 year and found to be stable. It is worth mentioning here that Li et al. have reported a template-assisted synthesis of Al NPs in an ionomer membrane.^[56]

Al NPs/Nanostructures Prepared Using Laser Ablation

Passivation of Al NPs by a minimal oxide cladding helps them to perform an active role in plasmonic applications. Negative real part and positive imaginary part of the dielectric function of these materials invoke the collective

Fig. 4 (a) TGA, (b) DTG, and (c) DTA plots of aluminum/PVP composite showing a two-stage oxidation (experiment under oxygen, nitrogen, and argon)

excitation of conduction electrons in the nanomaterials, and those collective oscillations are said to be localized surface plasmon resonances (LSPRs). It is well known that gold and silver support the LSPR in the ultraviolet (UV)–visible (Vis) and near-infrared (IR) part of electromagnetic spectrum. Recently, Al was also found to show an entire plasmon band in the UV–Vis–near-IR region that depends on the size and shape of the nanomaterial.^[71–73] Al is well known for its sensing applications, but very few experimental works have been reported in recent literature toward device preparation. Al NPs can support surface plasmons in Vis as well as UV and is capable to act as a suitable platform to surface-enhanced fluorescence and active elements in UV surface-enhanced Raman spectroscopy.^[74–76] Many biomolecular entities, fluorophores absorb in the UV spectral range and, consequently, support the surface plasmon resonances in the UV region of electromagnetic spectrum in biosciences. Simultaneous fabrication of NPs and nanostructures (NSs) is possible with ultrafast laser ablation of metals in liquid (ULAL) media. Depending on the laser parameters (wavelength, pulse duration, energy, beam waist, polarization) and liquid parameters (polarity, viscosity, etc.), nanomaterials of interest can be fabricated. Laser ablation of metals in aqueous media result in fabrication of a wide-range of NPs (with a broad size distribution) compared to the well-known chemical methods.^[74]

Preparation of Al NPs was achieved by laser ablation technique using short laser pulses and is described as follows: Al target was placed into a Pyrex cell and covered by a layer of absolute liquids— CCl_4 , CHCl_3 . After ensuring that the sample was perfectly parallel to the top of the optical bench, laser pulses (~ 40 fs) were allowed to focus onto the Al target surface using a plano-convex lens ($f = 8$ cm). It is difficult to adjust the focus exactly on the surface of the Al target immersed in liquid since the refractive index of the medium displaces the focal plane beyond the position of the focus in the absence of liquid. This displacement of the focus results in the poor rate of ablation and, consequently, lower yields of NPs. To avoid this, the focal plane is to be adjusted by displacing the target position or lens position. The estimated beam waist (ω_0) at the focus in air was ~ 15 μm . The liquid level was ~ 2 – 3 mm above

the surface of Al target. Al targets were placed perfectly normal to the laser beam on a motorized X–Y stage, which were operated through the motion controller. Typical pulse energies utilized were of ~ 250 μJ . The estimated fluence (corresponding to the input pulse energy of ~ 250 μJ and the beam waist of ~ 60 μm) at the focus in liquid media was 2.2 J cm^{-2} . The scanning speeds of the X–Y motorized stages were 0.2 and 0.4 mm s^{-1} . Both the stages were translated by the Newport ESP 300 motion controller. The motorized stages (Newport) were translated to write periodic lines on the Al sample, at a separation of ~ 150 μm . The time of exposure was about 5 min, and each scan resulted in 20 periodic lines. After the ablation, laser-exposed Al targets were removed from the liquids and preserved after a nominal cleaning. The liquids in which the ablation was carried out turn to golden-yellow color due to the dispersion of ejected Al NPs into the liquid.^[75] The coloration of the colloidal solution of CHCl_3 was thicker (dark yellow) compared to CCl_4 colloidal solution. Following the ablation, Al colloidal solutions were characterized by UV–Vis spectrometer, energy-dispersive spectrometer (Oxford Instruments), and laser-exposed portions were characterized by FESEM (Ultra 55 from Carl ZEISS) instrument. UV–Vis spectra confirmed the presence of Al NPs through exhibiting LSPR peak with a significant absorbance. EDX spectra were utilized to identify the constituents of the NPs. FESEM analysis demonstrated the formation of mushroom-like structures on the laser-exposed portions as reported earlier by Stratakis et al.^[76,78]

Characterizations of Al NPs in CCl_4 and CHCl_3

During the ablation of Al target in chloroform, the colloidal solution gradually became opaque and finally turned to pale yellowish (exposure time of ~ 5 min). In the case of CCl_4 , the solution became opaque faster compared to CHCl_3 and finally remained gray-yellow in color as shown in Fig. 5a. Figure 5b demonstrates the golden-yellow coloration of laser-exposed portion of the Al target. Visible comparison of synthesized Al colloids demonstrated that the sample in CCl_4 was darker in color than that in CHCl_3 . Thus, prepared colloidal solutions of Al NPs were

Fig. 5 (a) Golden-yellow coloration of Al colloids in CCl_4 and (b) golden-yellow coloration on laser-exposed portions of Al target

taken on a carbon tape (a drop of colloidal solution) for scanning electron microscopic (SEM) imaging, and the data obtained emphasize the fact that well-dispersed Al NPs with different sizes ranging from 5 to 30 nm were generated as shown in Fig. 6.

Size distribution of Al NPs was retrieved from the analysis of FESEM images by ImageJ software, and more than 300 number of particles were considered for analysis. The size distributions [shown in the inset of Figs. 6(a) and 6(c)] of 20–55 nm (in CCl_4) and 10–35 nm (in CHCl_3) were obtained from the FESEM data. In the former case, the average size was 33 ± 5 nm, whereas in the latter case, it was 15 ± 4.5 nm. The reason for narrow distribution of NPs in CHCl_3 compared to CCl_4 was the polarity of its molecules. Since CHCl_3 is a polar solvent, the molecules are

strongly attracted by the charged surface of Al NPs forming electrical double layers (EDLs)^[27] on the surface of NPs. Thus, formed EDLs cease the further growth of NPs as they screen the surface of the NPs from the ions, atoms, and molecular clusters formed due to the nucleation at the site of plasma. The formed EDLs on the surface of the NPs after and during the nucleation might not support the aggregation by passivation of the surface of NPs. For this reason, the growth of the NPs could be stopped, and thus, Al NPs with narrow size distribution with less average sizes were observed in the case of ablation in CHCl_3 .^[77] Furthermore, EDLs improve the stability of the fabricated Al NPs in polar solvents.

In contrast to CHCl_3 , CCl_4 is a nonpolar solvent (zero polarity of the molecules) and, therefore, could not prevent

the further growth of NPs generated after nucleation. Consequently, the growth of Al NPs could have taken place until the availability of free atoms, ions, and molecular clusters in the colloidal solution. Consequently, the size distribution of Al NPs in CCl_4 was broad compared to that in CHCl_3 . Energy-dispersive X-ray (EDX) spectrum was taken for both the colloidal (CCl_4 and CHCl_3) drops. Elemental constitution of fabricated Al NPs was examined by the EDX spectrum shown in Fig. 7. EDX spectrum confirmed the metallic nature of the fabricated Al NPs in CCl_4 and CHCl_3 . From the EDX data, we could conclude that the metallic nature of the Al was more dominant than the oxygen content in the generated NPs. Comparatively, less oxidation was observed in the case of Al NPs fabricated in CHCl_3 . Thus, Al NPs with minimal oxidization effects were fabricated in CHCl_3 and CCl_4 . Colloidal solutions were preserved in a closed container to prevent them from atmospheric oxygen, which causes further oxidation. UV-Vis absorption spectra of Al colloidal solutions are presented in Fig. 6b (CCl_4) and d (CHCl_3). Earlier reports on colloidal Al NPs synthesized in ethanol and acetone demonstrated the LSPR peak near 210 nm, due to the presence of Al NPs but not due to alumina.^[78] Baladi et al.^[78] observed that colloids of Al NPs exhibited a characteristic LSPR peak near 300 nm. UV absorption peaks of the colloidal solutions of CCl_4 (shown in Fig. 6b) were close to 300 nm (weak) and CHCl_3 (Fig. 6d) depicted one peak near 235 nm and another weak peak at 270 nm.^[79] The remaining peaks in the spectrum might be from the bond dissociations of the surrounding liquid molecules. LSPR peak position depends on the size of NPs and their dielectric function as well as the dielectric function of the surrounding liquid media. The red shift in the SPR peak in the case of Al colloids in CCl_4 compared to CHCl_3 can be explained on the basis of the size of NPs. When incident light shines on a large NP (as in the case of

Al NPs in CCl_4), the field stimulates the quadrupole and octupole plasmon oscillations rather the dipole oscillations because the incoming light field cannot polarize the NPs homogeneously.^[80] Peak positions of these higher order modes remained at lower energies (or longer wavelengths). For this reason, the plasmon resonance wavelength and bandwidth increase with increasing particle sizes. Consequently, we concluded that the average size of Al NPs in CCl_4 (nonpolar) was greater than in CHCl_3 (polar). This was confirmed from the FESEM images of a drop of Al colloids and their size distribution histograms. The average sizes of Al NPs obtained in CCl_4 and CHCl_3 were 33 ± 5 and 15 ± 4.5 nm, respectively. LSPR peak positions from UV-Vis absorption spectra and average size distributions of Al NPs obtained from ImageJ processing of FESEM images demonstrated that ablation of Al target in polar aqueous medium could have supported the fabrication of NPs with smaller sizes than that in nonpolar medium. Another advantage is that Al NPs fabricated in polar liquids restricted the oxidation over a long period due to the presence of EDLs on the surface of NPs. In higher polar liquids, NPs with higher stability can be obtained without any precipitation for a longer time. Stratakis et al.^[79] achieved highly stable AL NPs by ablation of bulk Al in ethanol using femtosecond and picosecond laser pulses. The average size of the NPs formed ranged from 20 nm for the femtosecond case to 60 nm for the picosecond case, whereas a narrower distribution was obtained with shorter pulses. They claimed that ultrafast laser structuring of bulk Al in various liquids could possibly be a promising method for efficient production of surface-passivated Al NPs.

Characterization of Al NSs

Laser-exposed portions of Al target acquired yellowish coloration, being visible at angles close to the normal

Fig. 7 EDX spectra of Al NPs fabricated in CCl_4 and CHCl_3 with ~ 40 fs pulses demonstrating minimal oxidation of fabricated Al NPs

incidence. The coloration of the Al strip was more pronounced when ablation was carried out in water at a fluence of $\sim 2\text{--}3\text{ J cm}^{-2}$ and at a scanning speed of 0.2 mm s^{-1} . In the case of Al target surfaces ablated in aqueous media other than water, the coloration of the laser-exposed portion was less pronounced. Observed coloration can be attributed to the SPR of the Al nanoentities present in the laser-exposed portion. This coloration can be assigned to structuring of the Al surface, and similar NSs with coloration were previously reported on Ag and Au.^[81,82] Depending on the focusing conditions, we observed different patterns on the Al substrate. Figure 8 illustrates the FESEM images of the laser-exposed portion on the Al substrate in CCl_4 and CHCl_3 , exhibiting a micro-grating with craters.

Within the micro-dimensional craters, a mushroom kind of NSs was observed. In general, the nature of liquid media influences the evolution of plasma, followed by nucleation and growth processes. Consequently, the morphologies of the laser-exposed portions which are the resultant of plasma evolution were examined by FESEM analysis. The FESEM images of the laser-exposed portions of Al targets ablated in CCl_4 (Fig. 8a and b) and CHCl_3 (Fig. 8c and d) demonstrated the microstructure formation and mushroom-like structures in their closer view. From the FESEM image shown in Fig. 8, it was observed that craters are the source points of explosive boiling wherein ballistic electrons are generated after the absorption of laser energy. These ballistic electrons

penetrate deep into the surface layer (approximately few microns) of target, and the melt thus formed explodes further to create craters. These micro-dimensional crater structures were observed only when the focus of the laser beam was exactly on the target surface. The magnified view of the laser-exposed portions of Al in both CCl_4 and CHCl_3 demonstrated mushroom-like NSs (Fig. 8b and d), tentatively assigned to Rayleigh–Taylor instabilities which, probably, occur between the vapor of the liquid and the metal melt.^[8] Under these instabilities, redistribution of the melt could have taken place resulting in the formation of mushroom-like structures.^[8] The exact origin of the obtained NSs is still under debate among the scientific community. The period of these mushroom-like structures was not uniform as illustrated in Fig. 8b and d. Stratakis et al.^[83] explained the reason behind the formation of mushroom-like structures due to pre-solidification of molten drop before transforming as a complete NP and to release into the surrounding aqueous medium. These kinds of NSs can be utilized in surface-enhanced Raman scattering (SERS) experiments after coating these mushroom-like structures with plasmonic metals such as gold or silver.

For a fluence of 2.2 J cm^{-2} and scanning speeds, ablation has been repeated in CCl_4 and CHCl_3 , but no coloration was observed on the laser-exposed portion of Al substrate, but the liquid in which ablation was carried out became yellowish. At lower fluence ($<0.05\text{ J cm}^{-2}$), virtually no changes of the Al surface and liquid were observed, even

Fig. 8 FESEM images of the laser-exposed portion in the Al substrate ablated in CCl_4 (a) and its corresponding higher magnification (b) and CHCl_3 (c) and its corresponding higher magnification (d)

with an increased number of laser shots. Average sizes of the obtained Al NPs and morphologies of Al NSs are explained on the basis of the formation of cavitation bubbles and their temporal oscillations in the aqueous media. One more possible explanation for the simultaneous crater and mushroom-like structure formation might be due to the energy density available at the center of the laser pulse and at the edges. As the energy density at the central part exceeds the ablation threshold, this part of the pulse creates craters due to a strong gradient in the intensity, whereas the side arms of the pulse comprise a moderate energy density just above the damage threshold causing a uniform bump/mushroom-like structures. At the points wherein energy density exceeds ablation threshold, ballistic electrons are created and penetrate deep into the metal surface causing the craters. The average sizes of Al NPs and shapes of NSs were elucidated on the basis of cavitation bubble dynamics obtained from our preliminary numerical studies and are explained in the following section.

Picosecond Ablation of Al in CCl_4 and CHCl_3

Ablation of Al was also carried out with ~ 2 ps laser pulses at 800 nm to confirm the influence of liquid polarity on the average size of NPs. The colloidal solutions obtained by ablation of an Al target with picosecond lasers were

different in appearance than the colloids prepared by femtosecond laser pulses. The Al colloids produced with femtosecond laser ablation look yellow in transmission, whereas those obtained with picosecond laser exhibited gray coloration at higher fluence ($\sim 2\text{--}3 \text{ J cm}^{-2}$) and yellow coloration at lower fluence ($\sim 1 \text{ J cm}^{-2}$). The coloration of the colloidal solution is determined by the dielectric function of the liquid medium (along with the dielectric function of the metal) in which ablation was taken place and laser parameters such as wavelength and pulse duration of the laser used. In both cases, the solutions were slightly opalescent and their opalescence increased upon increasing the laser fluence, which could be due to the higher yield of NPs. Prepared colloids were stable against sedimentation for at least 8–12 weeks even without addition of any surfactants. In the case of Al colloids in CHCl_3 , the stability was a bit higher compared to CCl_4 . Figure 9 demonstrates the FESEM images of Al NPs fabricated in CCl_4 and CHCl_3 using ~ 2 ps laser pulses at 800 nm and the corresponding images of laser-exposed portions. Figure 9a shows the FESEM image of Al NPs fabricated in CCl_4 and the inset represents the size distribution histogram demonstrating an average size of 24 ± 5 nm; UV-Vis absorption spectra demonstrated the LSP resonance to be near 350 nm. Figure 9b illustrates the FESEM image of Al NPs fabricated in CHCl_3 and the inset showing the size distribution

Fig. 9 FESEM images of Al NPs in (a) CCl_4 (insets showing the size distribution histogram and UV-Vis absorption spectrum of Al colloids in CCl_4) and (b) CHCl_3 (insets showing the size distribution histogram and UV-Vis absorption spectrum of Al colloids in CHCl_3). histogram demonstrating an average size of 14 ± 3 nm. UV-Vis absorption spectra demonstrated the LSP resonance to be near 324 nm. Figure 9c and d illustrates the surface morphologies of laser-exposed Al targets in CCl_4 and CHCl_3 , respectively, exhibiting slightly ordered microstructures. Laser-exposed portions exhibited micro-grating structures which were dissimilar to the random grating formed by femtosecond ablation of Al

ENERGETIC APPLICATIONS OF AL NPS

In most of the solid rocket propellants (SRPs) and high-explosive (HE) formulations, a combination of fuels, basically a reducing agent, which when oxidized will yield high energy, is incorporated. Thus, metal powders are one of the major ingredients in the SRPs and HE formulations. Particularly, powdered Li, Be, B,

Mg, Al, and Zr are of interest. A glance at the heats of combustion ($\Delta_c H$) of these metallic elements (see Fig. 10), with oxygen, implies that metals are one of the most desired fuel additives for SRPs and HE formulations. The combustion energy is the negative of the heat of formation ($\Delta_c H$), which is commonly expressed in kJ g^{-1} . The propellant efficiency, usually determined in terms of specific impulse (I_s), is the total impulse per unit weight of the propellant. It is well known that the I_s is directly related to the square root of calorimetric value or heats of combustion ($\Delta_c H$) and flame temperature (T_f) of the propellant, inversely related to the molecular weight of the combustion products.^[84,85] The demand for low-molecular-weight and high heat of combustion limits the desirable products to the first three periods of the periodic table. Another reason that makes Al a desirable candidate is the lower heat of fusion and heat of vaporization. Hence, Al is most widely used in practice due to its inherent practical and technical advantages over the other metals. The energetic applications of metallic Al include SRPs, HE formulations, and pyrotechnics (thermites). Though the applications are different, the major role metallic Al plays in the formulations is that of a reducing agent.

Chemistry of Aluminum Combustion

During the combustion reaction, the Al gets oxidized to its most stable oxide Al_2O_3 , but the first products at the flame zone are Al sub-oxides, such as AlO , Al_2O , and AlO_2 . The reaction mechanisms usually envisaged for the conditions prevailing in rocket motors are given in Eqs. R1–R17.^[86] Schematic diagram of the combustion process around an Al particle given by Beckstead et al.^[87,89] is shown in Fig. 11.

Fig. 11 Schematic diagram of Al combustion

Widener et al.^[88] have considered the following reactions for modeling the Al combustion.

Surface reactions

Gas-phase reactions

Dissociation reaction

Condensation reactions

Global reactions

Al gets oxidized by one or all of the reactions (R18–R19) with O_2 , H_2O , or CO . Beckstead et al.^[89] in their summary of Al burning emphasized that the effect of oxidizer is pronounced with oxygen being twice as effective as water and about five times more effective than carbon dioxide. The observed effect of pressure and initial temperature is minimal. The major difference between Al combustion and other metal combustion is the condensation of the aluminum oxide product and the subsequent deposition of part of the condensed oxide. Out of the early studies conducted in the 1960s and 1970s, significant information was obtained regarding the burning mechanism of Al. According to Glassman et al.,^[89,90] the

Fig. 12 Burning time of Al at different oxygen concentrations
Source: Reproduced with permission from Prentice, J.L. *AIAA 12th Aerospace Sciences Meeting*, AIAA Paper No. 74-146, 1974. Copyright © AIAA.^[93]

“D²” law (Eq. 1) is valid in the case of Al combustion, and the ignition and combustion depend on the melting and boiling points of the metal and the oxide. Gremyachkin et al.^[91] accounted for the effects of O_2 , H_2O , and CO_2 as oxidizers, concluding that the burning times for CO_2 are twice as long as for water, and that the burning times for water are 1.5 times as long as for oxygen. Davis^[92] concluded that the ambient oxygen concentration was more important for the particle combustion rate than the ambient temperature. Prentice^[93] conducted experiments using 250 μm particles and showed an inverse relation with oxygen concentration and the burning time. Also, Bucher et al.^[94,95] have shown that the flame zone thickness, which is also an indicator of the pace of the kinetics, varies with each oxidizer. Prentice et al.^[96] studied the effect of oxygen concentration on combustion at one atmosphere with 250 μm Al particles, the other gas being nitrogen or argon. The results summarized in Fig. 12 show a very pronounced effect of oxygen concentration.

Why Nonaluminum

Though Al reacts readily with steam to give aluminum oxide and hydrogen gas, the reaction does not always occur. This is due to the thin but strong solid layer of aluminum oxide being coated onto the entire surface of the metal particle, thus preventing the reaction. Not only the aluminum oxide melting temperature ($T_m = 2072^\circ\text{C}$) is more than that of Al ($T_m = 660^\circ\text{C}$), but the oxide has also almost twice the density of the metal. This prevents the metal diffusing through the oxide layer. According to Brooks et al.,^[90] Al ignition can follow two potential pathways: (1) the destruction of the protective oxide coat to allow the Al to be exposed to the oxidizing atmosphere or (2) the self-heating of the particle due to oxidizer diffusion through the oxide coat. Though the relative importance of these two pathways remains disputed, Brooks et al.^[90]

indicate that the destruction of the metal oxide coating, rather than the self-heating, is the dominant mechanism. Also, the particle surface temperature does not exceed the dissociation temperature of the oxide but is above the melting point of the oxide. Consequently, the oxide exists in a molten state throughout.^[89] For successive complete oxidation reaction and combustion to occur, heat needs to be supplied through this layer to unreacted Al below the layer, and the layer is broken due to the vapor pressure of the molten Al.^[88] Hence, it is presumed that the aluminum oxide inhibits ignition up to the melting temperature of the oxide, resulting in ignition and combustion.

The aluminum (Al) particle diameters in the propellant are generally in the 30 micron range. The oxidation of the aluminum particles tends to occur over much longer timescales than the conversion of the primary propellant (oxidizer/binder/fuel/plasticizer), during which time the particles are moved away (by convection) from the burning surface. When burning at elevated pressures as rocket motors are designed to operate, the propellant burns rapidly and aluminum particles are likely moved away (by convection) from the surface as they are exposed. When burning at ambient conditions, it has been observed that the aluminum particles generally tend to stay on the surface of the propellant without burning for a longer period of time. These particles cluster together to form larger agglomerates and are then lofted into the plume where burning takes place.^[96]

Belyaev et al.^[97] demonstrated that the burning time of individual Al particles in a high-temperature gas flow is independent of the pressure up to 20 atm and the temperature up to 1750°C. However, it strongly depends on the relative concentration of active oxygen-containing products such as H₂O and CO₂. Belyaev et al. also suggested a formula to calculate the Al particle burn time, usually referred as “the ‘D²’ law in Al combustion.”

$$\tau = 0.67 \frac{D^{1.5}}{a_k^{0.9}} \quad (1)$$

where D is the particle diameter in micrometers, a_k is the relative concentration of CO₂ and H₂O in the gas, and τ is the burning time in milliseconds. This relation point toward the advantage of using particles with smaller diameter to lower the burn time or in other words for faster burning and subsequently faster energy release. Apart from this, Lai et al.^[98] determined the melting point depression of Al clusters with respect to particle size (see Fig. 13). They have found that the melting point of these small Al clusters is significantly reduced, by as much as 140°C compared to the bulk values. The experimental findings are explained in terms of two models. The first model is based on classical thermodynamics and takes into account the surface/interface energies of a particle when evaluating the total free energy of the system. This model predicts that under equilibrium conditions each particle will consist of two

Fig. 13 The melting point as a function of Al cluster size
Source: Reproduced with permission from Lai, S.L.; Carlsson, J.R.A.; Allen, L.H. *Appl. Phys. Lett.* **1998**, 72(9), 1098–1100. Copyright © AIP Publishing LLC.^[98]

phases: a solid inner core and a liquid outer shell layer.^[99] The second model is based on the molecular dynamic methods^[100] and evaluates the individual state of an ensemble of identical particles. In this approach, each particle fluctuates between the two states over long periods of time. As discussed, the melting point also has a significant bearing on the combustion of Al because lowering the melting point would result in the earlier melting and vapor pressure generation and subsequent breakage of oxide layer. Though the effect of pressure and initial temperature is minimal on the combustion process, the exponent of the particle diameter dependence on the burning time is not a constant and changes from about 1.2 for larger diameter particles to 1.9 for smaller diameter particles.^[97,98] This is a significant observation in terms of the particle size reduction and its implication for the nonaluminum (nAl) burning.

Effect of nAl in Burning of Propellants

The burning rate of SRP is governed by Vieille’s law, $\dot{r} = aP^n$, where the burning rate ($\dot{r}$) is empirically expressed as being proportional to the pressure (P) raised to the pressure index (n). The pressure index (n) of the burning rate is stated to be independent of the pressure (P) and temperature (T). The constant of proportionality (a) for this law is said to be dependent on the temperature (T) of the propellant during burning. The use of nAl in the combustion of composite solid propellants has gained recent attention, and the reason may well be anticipated from the advantages of nAl combustion. De Luca et al.^[101–104] have extensively studied the effect of nAl on the burning rate of composite solid propellants, which has been recently summarized in.^[105] De Luca et al.^[104] conducted studies on the aluminized composite solid propellants with 83% solid loading which contained 15% Al. Bimodal Al size distributions were based on a mixture of micrometric (coarse) and nanometric (fine) particles, with coarse particles being typically in the range of 30–50 μm and fine particles in the range of 100–200 nm. The coarse-to-fine

ratio was one of the varied parameters. The experimental results in the nanometric range show a remarkable steady increase in the burning rate with increasing replacement of micrometric particles by nAl (data presented in Fig. 14). They concluded that usually metal powders above the micrometric range burn according to a distributed mechanism, extending much beyond the gas-phase flame thickness and, thus, essentially not affecting the heat feedback to the burning surface. The fact that nAl particles increase the steady burning rates indicates that the heat feedback is increased by the combined effects of possible earlier ignition^[106] and more rapid burning. Continuing the exhaustive studies on the effect of nAl on propellant burning. Galfetti et al.^[105] prepared different propellant compositions with a reference composite formulation consisting of 68% ammonium perchlorate (AP), 17% hydroxyl-terminated polybutadiene (HTPB) binder, and 15% Al. A bimodal size distribution of AP particles and mono/bimodal size distribution of Al were used in the compositions. The details of size distributions are tabulated in Table 1.

The nominal particle size of the Al was varied from 0.2, 0.4, 0.8, to 2.5 μm in the propellant formulations. The burning rate obtained for the propellant with the nominal sizes of 0.2 and 0.4 μm was found to be similar (data shown

Fig. 14 Increasing steady burning rates with decreasing coarse-to-fine ratio of Al powders

in Fig. 15). However, the actual reason was revealed when SEM analyses confirmed that the average dimension of both these Al powders is around $1.7\ \mu\text{m}$. Galfetti et al.^[105] concluded that a detailed characterization of the powders is needed to determine the real average particle size, and in absence of such detailed characterization, it can lead to incorrect interpretations. Pivkina et al.^[107] studied the burning rate of compositions based on an AP/Al stoichiometric mixture—74% AP+23.4% Al (μm size) + 2.6% C or 76% AP+24% Al/C nanocomposite (90% of nAl and 10% of carbon)—in a nitrogen atmosphere at a pressure of 1–6 MPa. The parameters considered were the average linear particle sizes of the components (d_{AP} and d_{Al}) and the porosity of the model compositions (ϵ) determined from the ratio of the calculated and real densities. The results showed (Table 2) a significant improvement in the burning rate is obtained by using nAl rather than using nano-sized AP particles. Jayaraman et al.,^[108] in their extensive studies, prepared a bimodal ammonium perchlorate-based

composite solid propellant formulation containing micron-sized Al and nAl, and their burning rates were compared in the 1–12 MPa pressure range (Fig. 16). Nanoaluminized propellants show 100% increase in the burning rate relative to nonaluminized or microaluminized ones, but only when large-sized coarse ammonium perchlorate particles are used. Burning rate plateaus observed in non- and microaluminized propellants are washed out with the addition of nAl, but the burning rates of nanoaluminized propellants register low-pressure exponents in the elevated pressure range. These results suggest that the heat feedback from diffusion-limited combustion of nAl particles near the propellant burning surface controls the burning rate of the propellant when sufficiently large parts of the burning surface are made up of the nanoaluminized fine ammonium perchlorate/binder matrix. The results collectively indicate that the burning rate of the propellant is controlled by the near-surface nAl combustion, which becomes diffusion limited in the elevated pressure range. These effects show significant changes in the pressure exponent of the burning rate with the addition of nAl over a wide pressure range than tested earlier.

Table 2 Summary of propellant compositions and burning rates

Sample number	d_{AP}	d_{Al}	ϵ (%)	u (mm s ⁻¹) ($p_0 = 1\ \text{MPa}$)
1	10 μm	97 μm	0.30	2.7 ± 0.1
2	35 nm	97 μm	2.65	2.5 ± 0.1
3	10 μm	10–50 nm	5.20	13.5 ± 0.4
4	35 nm	10–50 nm	5.20	26.5 ± 0.8

Effect of nAl on HE Formulations

It is long known that the addition of Al particles to explosive compositions improves their efficiency by enhancing blast effect and underwater performance. Ritter et al.^[109] report that some studies on the influence of particle size and Al content on the performance and handling properties as well as of different explosive formulations were discussed

Fig. 16 Comparison of the burning rates of propellants with (a) micro- and (b) nano-sized Al

in the 32nd International Annual Conference of Fraunhofer Institute for Chemical Technology (ICT).^[110–112] Ritter et al.^[112] studied the effect of Al particle size and shape on bis(2,2,2-trinitroethyl)nitramine (BTNNA)-HMX formulation. They reported a slight lowering of detonation velocity (VoD) and Gurney energy when ultrafine Al (ALEX) was used in the formulation. However, Brousseau^[113] showed that in the TNT/Al mixes, the addition of nAl increases the VoD and the heat of detonation. When nAl (ALEX) with particle size 100–200 nm was used in place of Al with particle size 12 μm, an increase of 6%–14% in the VoD was observed (Fig. 17). Apart from the improvement in the VoD, they also report a slight improvement in the heat of detonation for formulations with nAl. The possibility of nAl to react earlier and faster than regular

micrometric powders in TNT/Al mixes is attributed to the observed improvements.

CONCLUSIONS AND FUTURE SCOPE

Synthesis route for the production of surface-passivated nAl is an important requirement in a wide range of scientific disciplines, and synthesis of nAl with complex shapes and functions has always attracted the attention and fascination of scientists. It is seen that the size, morphology, stability, and properties (chemical and physical) of the nAl are strongly influenced by the experimental conditions, the kinetics of interaction of metal ions with reducing agents, and the adsorption processes of stabilizing agent with metal NPs. Many techniques are reported for the synthesis of nAl, and the studies indicate that specific molecular interactions at particle growth interface can result in the controlled nucleation and surface passivation of nAl particles. Molecular additives, either small molecular organic species or long chain polymers, have been found to exert strong influences on the shape, size, and surface properties of nAl. Usually, these “capping agents” are selectively adsorbed on special faces of the nAl through weak van der Waals interactions. Organic additives such as polymers, surfactants, or low-molecular-weight compounds are known to protect nAl oxidation and have been extensively investigated to modify the surface properties of nAl. Some of the recent reports emphasize the importance of Al NPs in energetic applications. Glavier et al.^[114] reported on the burning rate performance and overpressure generation for four kinds of nano-thermite powder mixtures. These mixtures were prepared using Al NPs mixed with three different

Fig. 17 Effect of the Al content on the VoD of TNT/Al mixes

nano-sized oxidizers, Bi_2O_3 , CuO , MoO_3 , and micron-sized polytetrafluoroethylene and compared with Al/CuO multilayer nano-thermite. Javed et al.^[115] investigated the effects of temperatures and various concentrations of Al NPs on the auto-ignition and combustion characteristics of heptane-based nanofluid droplets.

There are many reported methods for the synthesis of surface-passivated nAl ,^[116] and some of the processes discussed could be utilized for large-scale production of nAl . Flannery et al.^[119] prepared Al NPs encapsulated with a coating by the plasma-enhanced chemical vapor deposition technique from toluene precursors. Many recent reports suggest different kinds of passivation methods; however, the exact atomic-scale mechanism

of these surface passivation is rather not certain or very complex. Over the past few years, the requirement for surface-passivated particles in the propellant, automobile, and different industries dealing with Al powder materials is drastically growing, and this gives a challenging demand for the production of surface passivation methods and, hence, a bright future. Al NPs and NSs (including the metal oxide NPs) are attractive due to their potential applications as low-cost plasmonic systems, solar cells, photodiodes, and so on.^[117–120] This property in combination with their broadband plasmonic functionality (absorption in visible to the deep-UV spectral range) entrusts the researchers to explore the physics and chemistry of such materials in depth.

Table 5 Quick Reference Table

S. No.	Materials studied	Synthesis method	Applications	Ref.
1	Energetic composites: nitrocellulose (NC)/ $\text{Al}-\text{CuO}$, $\text{NC}/\text{Al}-\text{Fe}_2\text{O}_3$, $\text{NC}/\text{Al}-\text{Bi}_2\text{O}_3$	One-step electrospinning	Enhanced burning rate of the propellants and specific impulse	[3]
2	Al NPs (19 nm)	DC arc discharge, laser ablation, and commercial aluminum nanopowders	1. As the particle size decreased, the rate constant increased and the activation energy decreased. This work provides a quantification of the known pyrophoric nature of fine metal particles. 2. For Al NPs smaller than 50 nm, the activation energy was ~ 32 (DC arc) to $\sim 25 \text{ kJ mol}^{-1}$ (laser ablation), and increased to ~ 175 (DC arc) and $\sim 120 \text{ kJ mol}^{-1}$ (laser ablation) for particles in the size range of 100–150 nm.	[4]
3	A laminate of alternating layers of Al NPs/copper oxide NP (CuO NPs) thermites in polyvinylidene difluoride (PVDF)	Electrospray layer-by-layer deposition method	Enhanced performance, with combustion propagation velocity correlated with decreasing layer separation	[5]
4	Nano-aluminum/nitrocellulose mesoparticles	Mesoparticles were made by electrospray and comprised Al NPs (50 nm) and nitrocellulose to form micron-sized particles	Demonstrated $\sim 35\%$ higher burning rates	[6]
5	Small Al NPs (diameters of ~ 10 nm)	Catalytic decomposition of an alane precursor	Embedded NPs were protected by the membrane structure from any significant oxidation for the composite films to exhibit surprising stability in ambient air. Further, they could be fully accessed in base water for the hydrogen production quantitatively.	
6	Ethanol and Al NPs	NPs were purchased from Argonide Corporation with an average particle size of 50 nm	2 wt% nano-aluminum led to a dramatic reduction in the ignition delay (90%).	[7]

Table 5 Quick Reference Table (*Continued*)

S. No.	Materials studied	Synthesis method	Applications			Ref.
7	Gelled nano-aluminum microspheres	Electrospray method	Material	Ignition time (ms)	Burn time (ms)	[8]
			Al (3.0–4.5 μm)	No ignition	0	
			Al powder (50 nm)	14.1	14	
			Mixture of nano Al and NC (10%)	7.2	14	
			Gelled particles (NC, 1% by mass)	13.2	18	
			Gelled particles (NC, 3 wt%, mean size: 2.0 μm)	3.5	46	
			Gelled particles (NC, 6.5 wt%, mean size: 3.1 μm)	1.1	56	
			Gelled particles (NC, 10 wt%, mean size: 11.1 μm)	0.3	64	
8	Pure Al NPs	Ultrafast ablation	1. Spherical pure aluminum particles ranging in size from 10 to ~200 nm diameter. 2. Ablation threshold for aluminum ~0.4 J cm⁻² for 180 fs pulses at 775 nm.			[9]
9	Trilayer [tris-(8-hydroxyquinoline) AlQ ₃ /Al anoislands/ AlQ ₃ structure sandwiched between two electrodes	Thermal evaporation	The thicknesses of bottom AlQ ₃ , top AlQ ₃ , indium tin oxide, and Al layers are estimated to be 70, 50, 400, and 200 nm, respectively.			[10]
10	A mixture of two microparticle materials (aluminum and nickel oxide) and nickel oxide microparticles coated onto an aluminum foil	Femtosecond laser irradiation	1. This mixing process opens up new possibilities where powders of different materials can be ablated to produce a mixture, the materials combining at the nanoscale. This can also be applied for 3D nanostructured metallic alloy formation where two or more immiscible materials can be combined at the nanoscale to form an alloy. 2. This new technique can lead to promising solutions for development of better biomaterials and bio-composites for custom-designed, functionally graded bone implants and skeletal repair and also for the nanostructured surfaces for cell culture and tissue growth.			[11]
11	Air-stable Al NPs capped with 1,2-epoxy-9-decene Five different molar ratios of Al and epoxy decene (1:1, 2:1, 5:1, 10:1, and 20:1) were tested.	Chemical method	1. TEM data confirmed that ~25 nm nanostructures were embedded in a covalently bound polymer matrix that served as a prophylactic barrier against water/air degradation, and Al solid-state NMR was used to nondestructively confirm the presence of both metallic Al⁰ and oxidized Al³⁺. 2. These core-shell nanomaterials also have high-active Al content along with extremely long shelf lives (up to 6 months upon air exposure).			[12]

Table 5 Quick Reference Table (*Continued*)

S. No.	Materials studied	Synthesis method	Applications	Ref.
12	Al NP coating by metallic Ni shell	Electroless deposition	1. Ni coating significantly decreased both critical ignition temperature and ignition delay time of Al NPs. 2. Prior to 400°C, the oxidation rate of Ni-coated particles is much lower than that of uncoated particles, causing increasing stability to oxidation in air during the storage period. 3. The burning rate of Ni-coated Al NPs is higher compared to uncoated particles, which leads to easier ignition and a decrease in total combustion time of Al particles.	[13]
13	Al NPs (20–130 nm)	Thermal evaporation	Demonstrated a novel method for the fabrication of self-assembled Al NPs with controlled sizes on the surface of Si and fused silica by an in vacuo annealing process. In contrast to ex vacuo annealing methods, this method enables separation of aluminum particles by postponing oxygen exposure.	[14]
14	Al nanopowders, passivated with: liquids—NC, oleic acid ($C_{17}H_{33}COOH$), and stearic acid ($C_{17}H_{35}COOH$)—suspended in kerosene, ethanol, and fluoropolymer; solids—boron and nickel; and gases— N_2 , CO_2 , and air.	Electrical explosion of wires (EEW) method	Aluminum nanopowders with a protected surface showed the increased stability to oxidation in air during the storage period and higher reactivity by heating.	[15]
15	Al NPs (20–40 nm); aluminum oxide NPs (40–50 nm). Oleic acid-passivated Al NPs (~30 nm)	Laser irradiation/ablation	Mass spectrometry results for the ammonium nitrate-based mixtures seem to indicate that the oleic acid-capped Al NPs are more reactive than analogous oxide-protected materials under transient heating.	
16	Aluminum nanopowders	EEW method	1. Electro-exploded aluminum nanopowders, passivated and/or coated with the non-inert reagents: NC, oleic acid ($C_{17}H_{33}COOH$), and stearic acid ($C_{17}H_{35}COOH$), which were suspended in kerosene, ethanol, amorphous boron, nickel, fluoropolymer, ethanol, and air. 2. In contrast to micron-sized Ni-coated Al powders, Al NPs, coated by Ni contained a lot of Ni (lower burning enthalpy), which were more oxidized. 3. ALEX, Al ($ArpH_2$), and Al (Al_2O_3) powders—passivated by air. 4. Al (Ni) and Al (B) powders—passivated by inorganic coatings. 5. Al (St Ac) ethanol, Al (St Ac) kerosene, Al (Ol Ac), Al(F), Al (ethanol), and Al (NC) powders—passivated by inorganic coatings.	[16]

Table 5 Quick Reference Table (*Continued*)

S. No.	Materials studied	Synthesis method	Applications	Ref.
17	n-Al (coated aluminum nanopowder, 20–50 nm) and g-Al (conventional aluminum powder, 31–37 μm)	The composite propellants consist of 14.5% mixture of HTPB + toluenediisocyanate + diisooctyl sebacate, 65.5% ammonium perchlorate (AP) and 20% Al powder. Propellant samples of size $2 \times 4 \times 10$ mm were ignited by a hot nickel–chrome wire.	1. Increment in burning rate of propellants containing n-Al powder gradually decreased with an increase in the pressure. 2. Due to increment in the burning rate at low pressure gradually larger than that at high pressure with increasing n-Al powder content, the pressure exponents of HTPB/AP-based propellants decreased. 3. Addition of n-Al powders to the propellant made the ignition temperature decrease. The average ignition temperature of N-1 propellant (g-Al: 20, n-Al: 0) is 309.5°C, but for N-4 propellant (g-Al: 11, n-Al: 9), it was 286.5°C.	[17]
18	Fuel droplets containing nano-sized (<100 nm) and micron-sized (1–200 μm) aluminum particles	Commercially purchased and mixed with fuels	Nanosuspensions remained stable for a much longer time than micron suspensions. Fragmentation of the primary droplet is much more intense for the ethanol/Al droplet than for the n-decane/Al droplet.	[18]
19	Ni_xAl_y^+ clusters with nitromethane The reactivity of Ni_xAl_y^+ clusters with nitromethane was investigated using a gas-phase molecular beam system.	Ni_xAl_y cluster cations were produced by sputtering a Ni_xAl_y target (50/50 wt%; ACI Alloys, Inc.) in the magnetron cluster source.	Cluster material was more reactive than micron- and nano-sized aluminum. The volumetric heat of combustion was calculated for $\text{Al}_{50}\text{C}_{12}$ and found to be significantly higher than RDX and aluminized plastic bonded explosive formulations.	[19]
20	Al NPs deposited on glass substrates (1 mm thick 16×16 mm ² float-glass substrates) Cylindrical NPs with diameters of 125–270 and 225 nm	Laser interference lithography	1. The variation of the diameter of cylindrical Al NPs exhibited a nearly linear shift of the surface plasmon resonance between 400 and 950 nm, which is independent of the polarization vector of the incident light. An increase in both the diameter of the individual Al NP and the period led to a steady red shift of the SPR. 2. The transmission spectra exhibit an asymmetric shape of the SPR with a sharp edge at the short-wavelength side of each dip. Transmission spectra of the Al NP arrays have been simulated with the finite-element method. 3. For the nanoparticles, the SPR was located at $\lambda_{\text{SPR}} = 450$ nm, whereas a polarization vector along the long axis exhibited two minima at 550 and 800 nm. 4. Particle diameter of about 230 nm generated an SPR at $\lambda_{\text{SPR}} = 800$ nm.	[20]
21	Al NPs fabricated on the quartz substrate. The size of the smallest fabricated particles was 40 nm.	Ultraviolet interference lithography	The structures, sizes down to 40 nm, exhibited strong and sharp particle plasmon resonances in the near- and deep-UV ranges. The plasmon resonance associated with the short axis shifts from 310 to 380 nm with increasing length, whereas the long axis resonance shifts from 425 to 495 nm. There were equal numbers of nanorods along two orthogonal directions. Raman scattering enhancement of Al NPs was theoretically predicted to be as high as 10^5 and below 400 nm.	[21]

Table 5 Quick Reference Table (*Continued*)

S. No.	Materials studied	Synthesis method	Applications	Ref.
22	Al NPs (nano-Al) and aluminum–copper nan alloys (nano-Al Cu) Both types of particles were spherical (100–200 nm). Passivation layers—amorphous layers of oxides—having a thickness of ~4–5 nm for nano-Al particles, and ~3–4 nm for nano-Al Cu.	EEW method	1. The general exothermic characteristics of nano-Al Cu were similar to those of nano-Al. 2. The ignition temperature of nano-Al Cu was higher than its eutectic melting temperature, and the melting was believed to be mainly responsible for the early ignition. 3. The comparison of the reactivity of both materials shows that nano-Al Cu was more reactive than nano-Al.	[22]
23	Al NPs	Wet chemistry-based method	The passivation agent played dual roles of trapping Al particles to keep them nanoscale during the alane decomposition and protect the Al NPs from surface oxidation post production. Al NPs with 1-methylpyrrolidine alane were less reactive. Dimethylethylamine alane was more reactive.	[23]
24	Aluminum nanopowder with average particle sizes of 44, 80, and 120 nm Spherical Al NPs with an amorphous oxide layer of passivation whose thickness was 2–3 nm.	By discharging and quenching aluminum plasma arc vapor in the argon gas	As the average particle size became smaller, the active aluminum content decreased rapidly, so 80- to 120-nm-sized aluminum nanopowder is used as an energetic material. A thermal behavior study was carried out using TGA and DSC analyses, and the results revealed the increased reactivity in oxidation by showing lower oxidation onset temperatures as the average particle size of the aluminum powder samples decreased.	[24]
25	Red phosphorus as an alternative reducing agent in nano-thermite compositions Compared to aluminum, the amount of oxygen fixed by phosphorus is 1.45 times higher.	CuO-based P-nano-thermites were prepared by physical mixing of copper(II) oxide NPs with micron-sized red phosphorus particles. The phosphorus content was varied from 16 to 50 wt%.	The impact on the sensitivity of CuO/P-nano-thermites was moderate (27–39 J), but their friction (<5–8 J) and electrostatic discharge sensitivities (<0.12–0.21 mJ) were extremely high. The use of smaller (submicrometric) phosphorus particles is believed to enhance the reactivity of these new thermites.	[25]
26	Isopropyl alcohol (IPA), toluene, and perfluorodecalin (PFD) 5-nm coatings on 80-nm Al NPs	Plasma-enhanced chemical vapor deposition	The coatings provide an excellent protection against the contact with NaOH and against 2-month-long exposure to high humidity. The materials are ranked in the following order: PFD > toluene > IPA. This order is observed with respect to the contact angle of water; the amount of metallic aluminum, as determined by TGA; and heat of reaction, as determined by DSC	[26]
27	Al NPs (36.8–12.7 nm)	Laser-induced liquefaction	1. The mean radius and the standard deviation of the NPs generated under these conditions increased from Au to Al to Ni from 10.4 ± 19.6 to 36.8 ± 29.0 to 53.7 ± 50.6 nm, respectively. The second system measured the NP size during femtosecond laser ablation in the flowing air. The mean radius and standard deviation of the Au, Al, and Ni NPs generated under these conditions increased from 1.9 ± 1.2 to 9.1 ± 9.1 to 21.7 ± 33.9 nm, respectively.	[27]

(Continued)

Table 5 Quick Reference Table (*Continued*)

S. No.	Materials studied	Synthesis method	Applications	Ref.
28	Al NPs (radii about 100 nm) in pentaerythritol tetranitrate or 2,2-bis[(nitrooxy)methyl]propane-1,3-diyl dinitrate matrix	Nd:YAG laser irradiation	- The introduction of $C_2H_2F_4$ gas during nanosecond laser ablation resulted in a narrower size distribution of NPs and a smaller mean size for all three metals. In particular, the radius of Al NPs reduced from 36.8 ± 29.0 to 12.7 ± 12.3 nm. - The optical penetration depth for Al, Ni, and Au at 355 nm laser wavelength is 6.5, 13.0, and 15.0 nm, respectively.	[28]
29	Particle range (1–50 μm) composed of layers of Al and oxidizer at the scale of 10–100 nm	Arrested reactive milling, physical mixing, and sol–gel methodology	Combustion velocities for particles obtained with self-assembly (nanorods) depicted superior performance.	[29]
30	Aluminum nanopowder (particle size ranging from 40 to 110 nm)	Discharging and quenching aluminum plasma arc vapor in the argon gas	- Spherical Al NPs with an amorphous oxide layer of passivation whose thickness is 2–3 nm. - Average particle size becomes smaller, the active aluminum content decreases rapidly, so 80- to 120-nm-sized aluminum nanopowder might be used as an energetic material	[30]
31	Nano-thermite formulations (e.g., Fe_2O_3/Al and Bi_2O_3/Al)	Purchased from Innovative Materials and Processes, LLC	The major chemical constituents of Al/Fe_2O_3 and Al/Bi_2O_3 nano-thermite compositions after combustion events and performed preliminary studies that relate the efficacy of transport of these residues in air or water. Ultimately, it was determined that nano-thermite residues from expanded Al/Fe_2O_3 formulations comprise particles generally larger than 75 μm consisting of a mixture of wuestite and corundum with hercynite, whereas Al/Bi_2O_3 formulations give rise to small (<5 μm) particles consisting of metallic Bi and Al_2O_3 . Nanostructured Aluminum Films: Deep Ultraviolet Absorption from Glancing Angle Physical Vapor Deposition

Stephen Stagon and Ryan Scherzer

Mechanical Engineering, University of North Florida, 1 UNF Drive, Rm 2500 Bldg 50, Jacksonville, FL, 32224, United States

Abstract

This entry reports on the facile fabrication and characterization of aluminum (Al) nanoparticle arrays that absorb strongly in deep ultraviolet. First, Al nanoparticle arrays are fabricated using glancing angle physical vapor deposition and have average diameters of ~30 nm. After subsequent annealing, the structures become oxidized on the exterior with an Al metal core. Ultraviolet visible spectroscopy is performed to characterize the optical absorbance of the structures before and after annealing. The as-fabricated structures show strong and broad absorption centered near ~230 nm, and annealing in air at 400°C results in tightening and blue shifting of the absorption peak. Additionally, annealing results in a decrease in overall absorption intensity. These new results may be potentially useful for tandem or plasmon-assisted photovoltaics.

Keywords: Aluminum thin film; Glancing angle deposition; Physical vapor deposition; Plasmonics.

INTRODUCTION

With the explosion of nanoscience and technology, materials that exhibit surface plasmon resonance (SPR) when nanostructured have come to the forefront of scientific and technological investigation.^[1] SPR is a phenomenon where electrons located near the surfaces of discrete nanostructured material domains begin to oscillate under the excitation of an external electromagnetic field.^[2] Often when SPR is activated, the material strongly absorbs the external electromagnetic energy.^[1] While many metals exhibit SPR when in discrete nanostructures, silver (Ag) and gold (Au) have been the most widely studied materials. Ag and Au exhibit strong SPR in the visible region of the electromagnetic spectrum and have minimal propensity to damping the resonance.^[3,4] Capitalizing on this unique property, many have used various nanostructures of Ag and Au for technologies that include surface enhanced Raman spectroscopy (SERS), plasmonic sensing, and plasmon-assisted solar photovoltaics.^[5–7]

More recently, the search has been on for alternative materials that exhibit SPR due to some inefficiencies with Ag and Au.^[3,4,8] First, Ag and Au raw materials are prohibitively expensive, especially when the end use may be for a disposable product. Additionally, Ag and Au nanostructures are mechanically and chemically delicate.^[9,10] When stored in air for extended periods of time, Ag nanostructures quickly become fouled with sulfur and tarnish, greatly damping their plasmonic properties.^[11]

Under thermal or electromagnetic excitation, Ag and Au nanostructures may also reshape or relax into bulk. When in bulk, Ag and Au exhibit very weak SPR and cannot be used efficiently for real devices. Finally, Ag and Au nanostructures only exhibit SPR in the visible and near-infrared portions of the electromagnetic spectrum, and are therefore missing a large amount of energy in the ultraviolet (UV) portion of the spectrum.^[3,4,8] The UV portion of the spectrum is particularly important as many organic molecules resonate, and can thus be detected, in this region and as a large amount of energy from the solar spectrum is UV.^[2,12] Thus, there has been an active search for a material or materials that are mechanically and chemically robust and that are capable of capturing some portion of UV energy.

Recent literature shows that several metals and metal nitrides have come to the forefront of investigation as robust absorbers in the UV region.^[8] Similar to Ag and Au, titanium nitride (TiN) and zirconium nitride (ZrN) nanostructures should theoretically absorb in the visible spectrum, but may also be tuned to lower wavelengths toward UV.^[8] Unlike Ag and Au, these two nitrides are mechanically and chemically extremely robust. Unfortunately, TiN and ZrN are unlikely to absorb deep into the UV region and are therefore not ideal for this region.^[8] Alternatively, aluminum (Al) arises as a viable candidate as theory predicts that it will absorb in deep UV when appropriately dimensioned.^[2,13,14] As an additional benefit, the authors have demonstrated in previous work that Al

nanorods are mechanically and chemically robust through the formation of thin Al oxide shell that protects the inner Al nanoparticle.^[15]

Theoretical reports in literature show that Al nanostructures may strongly absorb across the entire UV region of the spectrum based on morphology and their spatial configuration.^[2,13,14] Ultimately, the ability to tune the plasmonic properties of the nanostructure is paramount to actual application. Theory, with the Bruggeman model and the Maxwell-Garnett model being the most commonly used, provides three main mechanisms by which the electromagnetic absorption of metallic nanostructures may be controlled.^[2] Here, we assume that the nanoparticles may be embedded in some medium, such as air, vacuum, or some other solid like oxide. The first mechanism of absorption control is size and shape of the particle. Theory predicts that particles with dimensions of <100 nm will strongly absorb in deep UV, with smaller diameters resulting in a stronger absorption at lower wavelengths and larger diameters at higher wavelengths.^[13,14] Al particles with diameters of 15 nm have theoretical absorption peaks as low as 215 nm, whereas those with diameters ~100 nm may begin to reach into the visible spectrum. The second mechanism of control is the medium in which the particle is embedded. For the case of Al nanoparticles within a native aluminum oxide shell, the increase of oxide thickness has been shown to lead to a red shift in absorption.^[2] Finally, the third mechanism of control is through interparticle coupling when adjacent particles are located in close proximity to one another.^[16] The spatial distribution of the electromagnetic field strength is affected by overlapping of the individual fields from each of the particles, and may be significantly stronger in areas of large overlap.

In this entry, we present a new facile method of creating Al nanoparticle arrays that exhibit controllable deep UV absorption. First, Al nanoparticles with diameters of ~30 nm and small interparticle spacing are grown using glancing angle physical vapor deposition. Subsequently, a level of control of absorption peak position in the UV is gained through subsequent thermal annealing in air to drive oxidation of the particles.

METHODS

Before presenting the results, we will first describe the methods of nanoparticle fabrication, annealing, and characterization. Al nanoparticle films are deposited onto fused quartz substrates using glancing angle thermal evaporation physical vapor deposition. First, 2.5 cm × 2.5 cm × 0.1 cm fused quartz slides are ultrasonically cleaned in acetone, ethanol, and de-ionized water and are then allowed to dry naturally in air. The slides are then placed onto a precision-machined glancing angle deposition mount, which is located at the top of the vacuum chamber. The vacuum chamber is a stainless steel cylinder of ~30 cm in

diameter and ~30 cm in height. The distance from the thermal evaporation source to the substrate is 20 cm, and the substrate normal is oriented at 85° relative to the source normal. The source material, 99.995% Al, is held in a tungsten boat at the bottom of the vacuum chamber. The vacuum chamber is then closed and pumped down using a turbomolecular pump and a mechanical roughing pump operating in series. The chamber is pumped down to a base pressure of 1×10^{-4} Pa and held there for 3 h to remove water vapor from the interior surfaces. Deposition is initiated by running current through the thermal source and is monitored by a quartz crystal microbalance located adjacent to the substrate, but at normal incidence to the source. The rate of deposition is controlled at 0.5 nm/s, and the total measured film thickness for the samples is 50 nm. After deposition is complete, the samples are removed from the chamber and subsequently characterized or annealed. Thermal annealing of the samples takes place in air on a temperature controlled hot plate, which uses a K-type thermocouple as a sensor. The hot plate is first allowed to reach 400°C and then allowed to stabilize for 30 min. Samples are then introduced to the surface of the hot plate and timing begins when the sample surface makes contact with the surface of the hot plate. Samples are oriented such that the Al nanoparticles are facing upward and are not in contact with the hotplate. Samples are annealed for durations of 5, 10, and 60 min, respectively, and timing ends as soon as samples are removed from the hot plate surface with tweezers. Samples are held in the air with tweezers for 5 min before being placed into plastic petri dishes. No contact is made with the sample surface at any time during annealing or characterization. Transmission ultraviolet-visible spectroscopy is performed using a Shimadzu UV-3600 Plus scanning from 185 to 700 nm, at the medium scan speed setting, with a 1 nm sample interval, and 1 nm slit width. Scanning electron microscopy (SEM) is performed on a Tescan Mira 3 operating at an acceleration voltage of 10 KeV, with a working distance of 1 cm, and using the in-beam secondary electron detector.

RESULTS AND DISCUSSION

As the first set of results, we show the morphology of the Al nanoparticle arrays through SEM micrographs, Fig. 1. Figure 1a shows a large area image, where individual nanoparticles are visible and large-scale uniformity is evident. Figure 1b shows the same sample at higher magnification to demonstrate the morphology of the individual nanoparticles. It is evident that there is a spread in diameters of the nanoparticles, with the average diameter being ~30 nm. The spacing between adjacent nanoparticles ranges from only a few nanometers to as large as ~10 nm. From previous studies, the authors note that the morphology of these structures is largely unchanged after thermal annealing in air at 400°C, which was verified by SEM in this entry although it is not

Fig. 1 SEM micrographs of the as fabricated Al nanoparticle arrays at (a) moderate magnification, the scale bar is 2 μm , and (b) high magnification, the scale bar is 200 nm. A small amount of Au is sputter deposited onto the surfaces prior to imaging to decrease charging and allow imaging

shown here due to extreme image charging.^[15] X-ray diffraction (XRD) from previous studies has also demonstrated that the nanoparticles are primarily oriented in the $\langle 111 \rangle$ out of plane orientation, which becomes weaker but still remains when the samples are annealed at 400°C.^[17] It should also be noted that previous XRD has not demonstrated any additional crystallization taking place, so any oxide shell that forms must be amorphous.

To support that the shell is amorphous and that metallic Al remains inside the particle, we present a transmission electron microscopy (TEM) micrograph and accompanying electron diffraction pattern of Al grown under the same conditions, except double the deposition thickness to allow for sample handling and removal from the substrate via sonication. This TEM study was performed on a FEI Tecnai T12 operating at 120 KeV. The bright field TEM image, Fig. 2a, shows a roughly round metallic core surrounded by a shell that lacks crystalline contrast and is likely amorphous. Corroborating this, the electron

Fig. 2 (a) A TEM micrograph of an Al nanorod annealed in air at 400°C for 30 min and (b) accompanying selected area electron diffraction pattern

diffraction image, Fig. 2b, shows a diffuse amorphous pattern at the interior and several sharp spots corresponding to the crystalline core, which is matched by the previously discussed XRD results.

Finally, we present the optical properties of these structures with their optical absorbance measured using UV-Vis spectroscopy, Fig. 3. Addressing the visible region of the spectrum first, with increasing annealing time the optical absorbance decreases, which is expected as the samples become increasingly translucent to the eye with increasing annealing time. No strong absorption peaks exist in the visible range of the spectrum. Moving to the UV range, the as-fabricated samples demonstrate a broad absorption peak centered near ~ 230 nm. The width of the peak is most likely due to the spread in nanoparticle diameter that is evident in the as-fabricated samples. As annealing is performed at 5 min, the overall absorption of the sample decreases and the peak becomes narrower and blueshifted, with a center near ~ 220 nm. The blue shift, corroborated by theoretical trends, is the evidence of a decrease in aluminum particle size. The decrease in overall absorption can

Fig. 3 Optical absorbance of the Al nanostructures measured using UV-Vis spectroscopy

be attributed to both a decrease in absorption cross section, through a decrease in metallic Al, and possible plasmon damping from the increase in oxide shell thickness around the Al particles. The tightening of the peak is also likely due to the transition of the smallest particles to predominantly oxide and their lack of contribution to the absorption as all Al metal is reacted. As annealing is increased to 10 min, a slight redshift occurs and the center of the peak again approaches ~230 nm. Theory predicts that as the thickness or development of the oxide shell increases, the absorption will red-shift. As annealing time is increased to 60 min, the UV/absorption peak diminishes and no distinguishable peaks remain, indicating a near complete loss of Al metal.

In passing, we will briefly discuss the use of this new structure for SERS and the possible technological implications of this structure. An attempt was made by the authors to use these structures as substrates for SERS, but it was unsuccessful. When a 325 nm excitation wavelength was used, the Raman signal was overwhelmed by fluorescence from the sample, and no Raman peaks could be identified. It may be unrealistic to attempt to use Al structures for UV Raman after having exposed the Al structures to air, due to oxidation and fluorescence generated by the laser-excited oxide. Alternatively, one area of applicability may be in tandem or plasmon-assisted solar photovoltaics. As the optical absorbance shows, this material allows a large amount of visible light to pass through and strongly absorbs the UV. When used in tandem with strong visible light absorbers or to enhance local electromagnetic fields through plasmon enhancement, large gains may be possible.

CONCLUSIONS

To summarize, this entry reports on the fabrication and characterization of Al nanoparticle arrays which exhibit strong absorption into deep UV. The arrays are fabricated using glancing angle physical vapor deposition with subsequent thermal annealing in air. Electron microscopy characterization shows that the particles are separated and have diameters of ~30 nm. UV-Vis spectroscopy shows that the as-fabricated particles have broad absorption centered near ~230 nm. After annealing, the particles absorption band tightens, initially blue shifts to ~220 nm after annealing for 5 min, and then returns to ~230 nm after annealing for 10 min. After 60 min of annealing, the samples no longer show absorption peaks and have a low level of broadband absorption. Although it is not applicable to SERS, this new knowledge can have potential impacts on plasmon-assisted or tandem photovoltaics.

Abstract

Aluminum metal matrix composites are materials frequently used in the automotive and aerospace industries due to their high strength-to-weight ratio, formability, corrosion resistance, and long-term durability. However, despite the unique properties of these materials, the lack of a reliable joining method has restricted their full potential in engineering applications. This article explores the effect of bonding time on transient liquid phase diffusion bonding of Al6061 containing 15 vol.% alumina particles using a 5 μ m electrodeposited Ni-coating containing nano-sized alumina particles as the interlayer. Joint formation was attributed to the solid-state diffusion of Ni into the Al6061 alloy followed by eutectic formation and isothermal solidification at the joint interface. Examination of the joint region using scanning electron microscopy, energy dispersive spectroscopy, and X-ray diffraction showed the formation of eutectic phases such as Al₃Ni, Al₉FeNi, and Ni₃Si within the joint zone. The results indicate that the addition of nano-size reinforcements into the interlayer can be used to improve joint strength. The joint strength recorded was 136 MPa at a bonding time of 10 min with a marginal increase in the shear strength when the bonding time is increased to 30 min.

Keywords: Aluminum metal matrix composite; Co-electrodeposition; Nanostructured.

INTRODUCTION

Metal matrix composites (MMCs) are used extensively in the design and construction of engineering components. The advantages obtained by using these materials instead of unreinforced metal alloys include superior mechanical properties such as high strength, high stiffness, high wear resistance, and very good elevated temperature properties leading to the development of low-cost Al-MMCs containing silicon carbide (SiC) or alumina (Al₂O₃) particle reinforcement, which has resulted in these materials being used in industries such as aerospace, automotive, sports goods, and marine. However, despite substantial improvements in the properties of such advanced materials, the lack of a reliable joining method that preserves the properties of these advanced alloys has restricted the use of Al-MMCs in engineering application.

Over the last decade, extensive research has been dedicated to identifying suitable joining techniques that maximize the potential of Al-MMCs. The quality or effectiveness of a joining process is assessed by its simplicity, soundness of the joint, size and geometry of the materials

that can be joined, and the resulting metallurgical and physical properties of the joint. Processes that have been used to join Al-MMCs include fusion welding processes, brazing, mechanical joining, adhesive bonding, and diffusion bonding. The use of fusion welding processes to join these advanced alloys is associated with difficulties such as high melt viscosity, segregation effects during resolidification, evolution of occluded gases causing extensive cracking in the heat-affected zone, weld porosity, and negative particle/matrix reactions producing brittle intermetallic compound. As an alternative to fusion welding, solid-state diffusion bonding has been attempted; however, the presence of tenacious and stable aluminum oxide layer at the faying surfaces inhibits metal-to-metal contact resulting in low joint strength. Slight improvements may be achieved with the application of high pressure.

The limitations experienced during solid-state diffusion bonding can be overcome by transient liquid phase (TLP) bonding, which applies an interlayer between the faying surfaces. Interdiffusion at the interlayer/base metal interface leads to an isothermal reaction that melts the interlayer/base metal interface thereby displacing the surface

oxides and facilitates metal-metal contact. The process has advantages of a low bonding temperature, low bonding pressure, and preventing the formation of heat-affected zones as well as minimizing the probability of unfavorable matrix/reinforcements reactions.

This article evaluates the effect of bonding time on the microstructure, microhardness, and shear strength of Al6061/Al₂O₃ joint bonded using a thin composite interlayer reinforced with nano-sized ceramic particles.

PARTICLE-REINFORCED MMCs

MMCs are materials with a continuous metallic phase (the matrix) into which a second phase (reinforcement) has been artificially introduced in the form of particles or fibers, mainly ceramics, with the objective being to improve the mechanical properties of the material. The properties of MMCs are comparatively superior to the unreinforced alloys.^[1] The properties of particle-reinforced metals containing short fibers (whiskers) are modest compared to the continuous fiber-reinforced MMCs; however, discontinuous reinforced materials are less expensive to fabricate and have more flexible production techniques. Thus, they are more cost-effective and can be exploited more easily than other types of composites. The factors influencing the type and form of reinforcement used are the material properties desired, ease of processing, and part fabrication. The stability between the components and the differences in their thermal properties such as coefficient of thermal expansion coefficient and thermal conductivity are the limiting factors in the compatibility of the two materials used to make the composite. A good bond can only be formed by proper and adequate interaction between the reinforcement and the matrix.

Dispersion-strengthened aluminum metal matrix composites (Al-MMCs) are produced by adding a secondary reinforcing ceramic or intermetallic phase to the aluminum matrix to improve the properties of the resulting materials as predicted by the rule of mixtures equation.^[2] The addition of a second reinforcing phase can result in the enhancement of mechanical properties such as Young's modulus, specific strength, wear and creep resistance, and thermal expansion.

The geometry of the reinforcement in MMCs has also been shown to markedly affect mechanical performance of the material and the matrix deformation behavior. The literature shows that matrix deformation between closely spaced elastic particles would be highly constrained resulting in localized stress levels that are many times the matrix flow stress that developed in response to external loads and vary appreciably with the geometry of the reinforcing phase.^[3,4] This change to the behavior of the matrix alters the yield strength and ductility of the composite, which has been shown to be directly proportional to the particle content of the MMC.^[3] Failure of particle-reinforced

Al-MMCs has been shown to be associated with particle cracking and void formation in the matrix within clusters of particles;^[4-6] however, this is more prevalent in coarser particles than in finer ones. The failure associated with particle clusters is attributed to the higher stress generated in these regions.

The strength achievable with the addition of second ceramic phase of SiC or Al₂O₃ is much greater than that achieved by precipitation strengthening. However, little consideration is given to the effect of reinforcements on the structure and properties of the heat-treatable matrix. Negative matrix/particle reactions during the fabrication process can deplete the precipitate-forming elements leading to the formation of high melting point intermetallics such as MgAl₂O₄ in the matrix of MMCs that are not dissolved by normal solution heat treatment.^[7-16]

When a MMC containing a ceramic reinforcement is cooled from the fabrication temperature, large tangles of dislocation are generated in the matrix due to strain induced as a result of the mismatch in the coefficient of thermal expansion of the ceramic reinforcement and the matrix.^[17,18] The induced strain results in the formation of high-energy dislocation sites that facilitates the nucleation of strengthening phases in age-hardenable alloys.^[9,11,12,19]

FUNDAMENTALS OF TLP DIFFUSION BONDING

TLP diffusion bonding requires that the faying surfaces are brought into intimate contact with a thin interlayer placed between the faying surfaces. The interlayer containing a melting point depressant (MPD) can be added in the form of a thin foil, powder, or coating^[20,21] that is tailored to melt by eutectic or peritectic reaction with the base metal. The liquid filler metal wets the base metal surface and is then drawn into the joint by capillary action until the volume between components to be joined is completely filled.

TLP bonding can be conducted using a pure interlayer or interlayer near the liquidus composition at the bonding temperature. The use of a low melting interlayer is commonly used since it reduces the overall process time by decreasing the solute to be diffused from the interface. On the other hand, the use of pure interlayer can be considered to be more effective in TLP bonding as the eutectic reaction at the interlayer/base metal interface is able to displace surface oxides during bonding. TLP diffusion bonding process was first divided into five discrete stages: heating, melting, dissolution of the base metal, isothermal solidification, and homogenization of the excess solute at the bond line. This was later condensed to three stages: base metal dissolution, isothermal solidification, and homogenization.^[22] In later work by MacDonald and Eager,^[23] the second and third

stages described by Duvall were combined to give four stages: heating, melting and parent metal dissolution, isothermal solidification, and homogenization. Zhou^[24] reclassified his earlier work to include a heating stage. The second stage was also expanded to be dissolution and widening.

Heating Stage

This stage of the process involves increasing the temperature of the material until the bonding temperature is reached. A model was developed by Niemann and Garrett^[25] that evaluates the interlayer width lost during the heating stage. This model showed that the volume of the interlayer loss during the heating stage of TLP bonding can be calculated using the following equation:

$$x \cdot \rho_c = 1.1284 \rho_a (C_{as} - C_m) (D_s t)^{\frac{1}{2}} \quad (1)$$

Where x is the thickness of interlayer lost through solid-state diffusion, ρ_c is the density of the interlayer, and ρ_a is the density of the substrate. In this equation, the diffusion coefficient is assumed to be constant; however, in reality the diffusion coefficient increases with temperature. A similar equation was developed by Tuah-Poku^[26] for predicting the interlayer thickness loss during the heating stage by using an effective diffusion coefficient. MacDonald and Eagar^[23] used a method proposed by Shewmon^[27] to determine the effective diffusion coefficient, D_{eff} , a value that compensates for the temperature changes and can be calculated by the following equation:

$$D_{eff} = \frac{\int_0^t D(t) dt}{t_o} \quad (2)$$

Where t_o is the total time of the heating stage. MacDonald and Eagar showed that during the heating stage, below 80% of the bonding temperature, the effects of diffusion on a reduction in the interlayer can be neglected, since diffusivity at this low temperature will be very slow. Hence, the temperature is given as a function of time starting from $0.8T_b$ as shown in Eq. 3, where τ is the heating rate.^[23]

$$T = \tau t + 0.8T_b \quad (3)$$

By substituting Eq. 2 into Eq. 3, the effective diffusion constant can be calculated from the following equation:

$$\frac{D_{eff} T_b}{\tau} = \frac{1}{\tau} \int_{0.8T_b}^{T_b} D_o \exp\left(\frac{-Q}{RT}\right) dt \quad (4)$$

Dissolution and Widening Stage

The scientific literature on TLP bonding has shown that there are no suitable analytical solutions for the dynamic temperature portion of dissolution stage. Since the concentration of the solute at the interfaces varies with temperature, it is very difficult to mathematically simulate the changes occurring at the interface during dissolution. Mathematical models of this stage of TLP bonding identified in the literature presented two important assumptions: (i) that the time required to reach the bonding temperature (T_b) is infinitesimally small, or (ii) that dissolution occurs only after the bonding temperature has been reached.^[43] By applying assumption (ii), Tuah-Poku et al.^[26] predicted that the time required for dissolution and widening of the interface [$X(t)$] can be calculated using the following equation:

$$X(t) = K \sqrt{4 \cdot D_L t} \quad (5)$$

The constant, K , is evaluated at the bonding temperature according to the phase boundaries of the equilibrium phase diagram. Using this assumption, the time for complete dissolution of the interlayer is given by the following equation:

$$t_2 = \frac{W_o^2}{16 \cdot K^2 \cdot D_L} \quad (6)$$

Tuah-Poku et al.^[26] also predicted the time required for homogenization of the liquid layer through widening of the base metal by assuming that the interface motion was diffusion controlled according to the general square root law shown in Eq. 7, where time (t) exponent could have a value other than 0.5.

$$X(t) = at^n \quad (7)$$

Where a is a general constant which combines the diffusivity and constant (K), and n is determined from the experimental results.

Isothermal Solidification with Stationary Interface

If the solid-liquid interface is assumed to be in a state of equilibrium, then the composition of the solid phase at the solid-liquid interface during the isothermal solidification stage is fixed by the tie-line on the equilibrium phase diagram since the solid-liquid interface is fixed with respect to the base material frame of reference, the total mass transferred across each interface can be determined by integrating the flux (J) over time to produce Eq. 9.^[26,28]

$$J = \int (C_{al} - C_o) \sqrt{\frac{Dt}{\pi}} dt \quad (8)$$

$$J = 2(C_{\alpha L} - C_o) \sqrt{\frac{Dt}{\pi}} \quad (9)$$

So a balance of the initial solute mass and the total mass transferred across the interface gives the following equation:

$$C_F \cdot W_o = 2 \cdot J \quad (10)$$

Therefore, Eq. 9 can be substituted into Eq. 10 and rearranged to give the following equation:

$$t = \frac{\pi}{16 \cdot D} \left[\frac{C_F \cdot W_o}{(C_{\alpha L} - C_o)} \right]^2 \quad (11)$$

Where D is the diffusion coefficient, W_o is the initial interlayer width, $C_{\alpha L}$ is composition of the eutectic form element at the interface, C_o is the original composition of the base metal, and C_F is the composition of the eutectic forming element remaining in the joint region. The published data on stationary models suggest that significant errors are associated with single phase solution since the migration of the solid-liquid interface is neglected, leading to an overestimation of the time required for isothermal solidification.^[29,30]

FACTORS AFFECTING TLP BONDING

TLP diffusion bonding is affected by parameters such as bonding pressure, bonding temperature, bonding time, and interlayer thickness and composition. The effective control of the bonding pressure is very important in TLP diffusion bonding. If the bonding pressure is too high, this could result in the liquid being squeezed out as soon as liquid phase is achieved, and the loss of the liquid from the interface limits the strength of the bonds that are formed.^[50]

During TLP diffusion bonding, the temperature is kept slightly above the eutectic temperature of the interlayer/base metal interface and below the solidus temperature of the base metal. The significance of bonding temperature can be attributed to the temperature required for liquid formation at the interface. Increasing the bonding temperature also increases the diffusivity of solute into the base metal and promotes the liquid formation at the interface and wetting of the parent metal.^[31,32] Huang et al^[38] reported that in the TLP bonding of SiCp-reinforced Al-MMC, the shear strength of the joint increased with an increase in bonding time and temperature until a temperature of 600°C was reached after which the shear strength of the joint started decreasing.

The interlayer design including its composition and thickness determines the removal behavior of surface oxide film, the particulate redistribution in bonded region, and the joining behavior between each micro-bonding

interface during TLP diffusion bonding. Scholars have studied the use of Cu interlayers for joining Al-MMCs since Al-Cu binary system forms a eutectic at 548°C.^[33,34] The success of Cu in displacing surface oxides has led to the use of Cu-based interlayers such as Ag-Cu,^[35] Cu/Ni/Cu^[36] composite interlayer, Zn-Al,^[37] Al-Si-W-mixed powder and Al-Si-Ti-SiC-mixed powder were used to improve the densification of the thick joining layer and to reinforce the thick joining layer by metallic phase and ceramic particulate.^[38]

Pure metal interlayers such as nickel,^[39,40] silver,^[41,42] zinc,^[20] and copper^[42,44] can react with metal surface by means of eutectic reaction to displace surface oxides. In joints using the above pure interlayers, the existing problems can be summarized as follows: (i) parent metal dissolution (ii) particulate segregation,^[42-44] (iii) void formation in particle-segregated region,^[41] and (iv) low-strength micro-bonds at particle-metal interfaces resulting from the poor wettability of molten interlayer on ceramic reinforcement.^[41,45] In recent years, interlayers such as Cu-Ni powders^[46] and Ni-Al₂O₃^[47] have been used to increase joint strength and decrease joint defects such as particle segregation. The geometry of the interlayer is another important criterion in TLP diffusion bonding.^[48,49] Bosco and Zok^[50] showed that there exists a critical interlayer thickness at which pore-free bonds are produced. The thickness of the interlayer must exceed that which is consumed through solid-state diffusion to ensure liquid is formed at the bonding temperature.

The required bonding time also ensures the completion of isothermal solidification in the joint centerline during TLP bonding.^[51,52] The duration of the bonding process may also lead to increased volume of solute atom present in the parent metal, which has been shown to improve joint strength relative to the strength of the base metal.^[38,53,54]

MATERIAL AND METHODS

This article uses an Al6061 alloy with a composition as shown in Table 1. The alloy contained 15 wt.% of alumina (Al₂O₃) dispersion (see Fig. 1). The alumina particles were angular with a size ranging from 5 to 30 μm as shown in Fig. 1b. The specimens were prepared for bonding by cutting to a dimension of 10×10×5 mm, prepared to 800 grit size SiC, and polished to 1 μm using diamond suspension polishing fluid and cleaned in an acetone bath.

The specimens were subsequently assembled at room temperature and placed on the lower platen within the induction coil. An ungrounded K-type Omega thermocouple was used to monitor the bonding temperature at the joint interface. Once a vacuum of 4×10^{-4} torr (0.053 Pa) was achieved. The specimens were brought to the joining temperature at a heating rate of 35°C/min and then held at that temperature for the time intervals ranging from 1 to 30 min. The power was turned off, and the specimen was

0.03	0.11	1.09	0.05	0.08	0.09	0.15	0.69	Bal

cooled to room temperature in vacuum once the bonding process was complete.

Bonded specimens were sectioned transverse to the bond line by an Allied abrasive saw and mounted in Bakelite. The mounted specimens were prepared according to ASTM standard B 253.^[55] They were ground on silicon carbide papers from 240 to 800 grit, followed by polishing with diamond suspension to 1 μm and etched with Keller's reagent.

Bonded samples were machined to eliminate edge effects. These specimens were machined to approximately 10 mm length and 8 mm diameter and pulled in tension by a Tinius Olsen tensile testing machine at a crosshead speed of 0.5 mm/min in position control mode such that the specimen experienced pure shear stress across the bond interface. The maximum load was divided by the bond area in order to calculate shear strength. For each bonding condition, three specimens were tested and the average value used to determine the shear strength (bond strength). Examination of the joints was performed using a Ziess optical microscope and a JEOL 8200 scanning electron probe microanalyzer. Quantitative analyses were carried out using energy dispersive spectroscopy (EDS).

Nanocomposite Interlayer

Nickel (Ni) was electrodeposited on to the aluminum substrate from a Watts nickel bath having the following composition: nickel sulfate (NiSO₄), nickel chloride (NiCl₂), boric acid (H₃BO₃), sodium dodecyl sulfate (SDS), and saccharin (C₇H₅NO₃S) baths were designed each containing 50 g/L alumina (Al₂O₃). The electrodeposition process was carried out at 50°C under constant magnetic stirring of 250 rpm to prevent particle agglomeration. Transmission electron microscopy (TEM) analysis of the nano powder prior to deposition identified regions of particle agglomeration as shown in Fig. 2b. Point counting analysis of the coating using ImageJ software indicated the presence of approximately 18 vol.% nano-Al₂O₃ particles within the coating.

BOND FORMATION

The results show that the joint formation during TLP diffusion bonding occurred over distinct stages: solid-state diffusion, melting and dissolution of the base metal, isothermal solidification, and joint homogenization.

Interfacial Contact and Solid-state Diffusion

During the first stage of TLP diffusion bonding, solid-state diffusion of the MPD will occur as the materials are heated from room temperature to the bonding temperature, results in a change in the composition of the joint interface as shown in Fig. 3 where three distinct reaction layers were identified at the aluminum interface. The formation of reaction layers (L₂ and L₃), shown in Fig. 3, occurred because of the interdiffusion of Ni and Al. EDS analysis reveals that L₁ is Ni-containing dispersed Al₂O₃ particles

Fig. 3 SEM micrograph of joint bonded using a 15 μm Ni–Al₂O₃ coating at 600°C for 1 min

after a bonding time of 1 min. L_2 , on the other hand, appears to be a Ni–aluminide with compositions of 50.67 (at%) Ni and 46.71 (at%) Al. L_3 contains approximately 24.31 (at%) Ni and 76.84 (at%) Al, which according to the Al–Ni phase diagram is likely to be NiAl₃ intermetallic. This compound is believed to form due to the low solubility of Ni in Al. The changes observed at the joint interface lead to the eutectic reaction and the beginning of the second stage of the bonding process.

Liquid Formation and Base metal Dissolution

Upon reaching a temperature of 565°C, NiAl₃ reacts with 88.4% Al and 2.08% Si to form a ternary eutectic liquid along the bond interface as predicted by Eq. 12.^[56] In this process, the NiAl₃ intermetallic is dissolved in the eutectic reaction and diffuses into the base metal. Continued heating past 577°C results in the formation of a second eutectic liquid which was predicted by Eq. 13.

Holding at a bonding temperature of 600°C resulted in increased diffusivity of the eutectic liquids into the base metal. Since the diffusion of Ni into the liquid phase is expected to be orders of magnitude faster than in solid, the composition of the interlayer changes rapidly through the interdiffusion of Ni and Al leading to dissolution of the base metal. Figure 4 shows the eutectic structure at the center of the joint, confirming the formation of the eutectic liquid during the bonding process.

Holding at a bonding temperature of 600°C caused the liquid phase to spread between the faying surfaces under the effects of both an external pressure and capillary action, increasing the bonded area and enhancing the diffusion of Ni and Al into the liquid phase. The continued diffusion results in base metal dissolution which increases the width of liquid phase. The presence of nanoparticle reinforcements within the interlayer reduces the volume of Ni within the joints and limits the liquid width formed

during dissolution. Segregation tendency is dependent on the relationship between the liquid film width produced at the bonding temperature, particle diameter, and interparticle spacing.^[21] When the liquid film width is large enough that sufficient particulate material is contained in the melt, particles will be pushed ahead of the solidifying liquid–solid interface resulting in particle segregation at the bond line. However, if the liquid film width is less than some critical value, segregation should not occur. Wavelength dispersive spectroscopic analysis across the joint zone as a function of bonding time indicates that the Ni volume at the joint center varied between 3.67 wt.% after 1 min and 0.15 wt.% after 30 min bonding time.

Isothermal Solidification

Figures 5 and 6 show the effects of bonding time on joints made at a bonding temperature of 600°C using a 5 μm thick Ni–Al₂O₃ coating as the interlayer. For a bonding time of 1 min, a large concentration of Ni remained at the interface after bonding as indicated by EDS analysis. When the bonding time was increased to 5 min, the volume of Ni remaining at the joint interface after bonding significantly decreased, suggesting complete diffusion of the Ni–Al₂O₃ interlayer into the base metal, leaving a small band of segregated particles at the interface (see Fig. 5b). The segregation of particles was accredited to the pushing of strengthening particles by the solidifying liquid–solid interface. Stefanescu^[57] showed that particle pushing can be assumed to be a steady-state condition under which the interface velocity can be assumed to be equal the rate of isothermal solidification. Further increase in bonding time to 10 min resulted in the elimination of the interface and an increase in the grain size within the joint, which disrupts the band of segregated particles at the interface (see Fig. 6a) and homogenized the joint zone.

Increase in the bonding time to 30 min resulted in a corresponding increase in the grain size (from 35 to 120 μm) within the joint region as shown in Fig. 6b. In the reported studies on TLP diffusion bonding of Al–MMCs, it was shown that the width of the segregated zone at the joint center increased with increasing bonding time. The opposite of this relationship was observed in this article.

Fig. 4 Eutectic liquid formation at the joint interface during TLP diffusion bonding

Fig. 5 Light micrographs of bond made with 5 μm thick Ni–Al₂O₃ at 600°C for (a) 1 min (b) 5 min

Fig. 6 Light micrographs of joint bonded with 5 μm thick Ni–Al₂O₃ 600°C for (a) 10 min (b) 30 min

The results show that the width of the segregated region decreased with increasing bonding time. This can be attributed to the heterogeneous nucleation of grains within the joint zone during solidification, leading to grain refining as grain size increases; during the homogenization of bonding, the micro-Al₂O₃ particles are pushed to the grain boundary areas disrupting the continuous band of segregated particles at the interface.

MECHANICAL PERFORMANCE OF TLP DIFFUSION BONDS

Microhardness Measurements

The degree of compositional homogeneity achieved across the joint region was assessed by microhardness testing. A uniform hardness across the joint would indicate good chemical homogeneity. Figure 7 shows the hardness profile of joints bonded as a function of bonding time.

The profile indicates that under all bonding conditions investigated, the maximum hardness number was recorded at the joint center. At a bonding time of 1 min, a hardness number of 146 VHN was recorded at the joint center and increased to 160 VHN when the bonding time was increased to 5 min. This change in the hardness number was attributed to the segregation of micro-Al₂O₃ particles within the joint region as well as the presence of nano-sized Al₂O₃ particles within the grain boundary as shown in Fig. 8.

Fig. 7 Microhardness profiles across the joint interface as a function of bonding time

Further increase in the bonding time to 10 min resulted in a reduction of the hardness number to 124 VHN. This reduction coincides with an increase in the grain size within the joint region. The addition of nano-sized particles to the joint region is expected to restrict grain growth by exerting a Zener pinning pressure at the grain boundary. When the bonding time was increased to 30 min, a hardness value of 162 HV in the joint center again increased. This increase was attributed to the formation of Al₃FeNi and Ni₃Al intermetallic compounds with the joint region as indicated by EDS analysis. Only slight variations were observed in the hardness of the base metal, which fluctuated between 81 and 94 VHN as a function of distance, measured from the joint center. Similar variations were observed in the

Fig. 8 (a) TEM image of the bonded joint when nano-sized Al₂O₃ particles are used in the interlayer and (b) TEM image of a nano-Al₂O₃ particle located at a grain boundary

Source: Previously published in the article K.O. Cooke "A Study of the Effect of Nano-sized Particles on Transient Liquid Phase Diffusion Bonding Al6061 Metal–Matrix Composite (MMC) Using Ni/Al₂O₃ Nanocomposite Interlayer" *Metallurgical and Materials Transactions B* June 2012, Volume 43, Issue 3, pp 627–634, Reprinted with permission from Springer.

untreated base material before joining. This suggests that the mechanical properties of the base metal outside the joint zone were not affected by the heating cycle.

Shear Strength Measurements

The shear strength profile of joints bonded as a function of bonding time is shown in Fig. 9. The results indicate that the shear strength increased from 63 MPa at a bonding time of 1 min to 136 MPa at 10 min bonding time. Further increase in the bonding time to 30 min resulted in a marginal increase in the shear strength to 138 MPa. The shear strength recorded at 10 min bonding time was attributed to a reduction in the grain size caused by recrystallization of the joint region and the presence of nano-sized ceramic particles at the grain boundaries exerting a Zener pinning pressure. The marginal increase in the shear strength recorded when the bonding time was increased to 30 min was attributed to the precipitation of brittle nickel aluminide phases (Al₃Ni and Al₃FeNi) within the

Fig. 9 Effect of bonding time on shear strength using 5 μ m thick Ni–Al₂O₃ coating bonded at 600°C

joint region. The literature suggests that beyond 30 min, the shear strength is expected to decrease as grain size increases and the ductility of the joint increases due to grain growth at the bonding temperature.

The fractured surfaces of the failed joints were analyzed to identify the mechanism of joint failure and composition of the failed surfaces. Figure 10a shows the fractured surface of a joint made at 1 min bonding time. The surface was characterized by brittle failure with evidence of plastic shearing presented as diagonal grooves indicating the loading directing. Cleavage planes were also observed as well as vacant pockets believe to be the sites of particle segregation during the bonding process. When the bonding time was increased to 5 min, the surface also showed characteristics of a brittle fracture (see Fig. 11), which propagated through the joint region resulting in the formation of cleavage planes. These observations were confirmed by X-ray diffraction (XRD) analyses shown in Figs. 10b and 11b which indicate the presence of high concentrations of brittle AlFe₆Si, Ni₃Si, and Al₂O₃ compounds at the fractured surface for bonding times of 1 and 5 min, respectively. Figure 12a shows the fracture surface of a joint bonded for 10 min. The surface is characterized by plastic shearing as well as fractured Al₂O₃ particles indicative of mixed mode of failure with evidence of both ductile and brittle failure occurring. XRD analyses shown in Fig. 12b indicate the presence of high concentrations of Al as well as small quantities of several intermetallic compounds including AlFe₆Si, Ni₃Si, and Al₂O₃. The large Al peak is believe to be responsible for the ductility observed at the fractured surface. Further increase in the bonding time to 30 min resulted in a mixed mode of failure with evidence of plastic shearing as well as particle clustering as shown in Fig. 13. XRD spectrum of the fractured surface also revealed the presence of Al₂O₃ particles combined with AlFe₆Si and Ni₃Si intermetallic compounds as shown in Fig. 13b. The

Fig. 12 (a) SEM micrograph and (b) XRD analysis of the fractured surface of a bond made with 5 μ m thick Ni-Al₂O₃ at 600°C for 10 min

Fig. 13 (a) SEM micrograph and (b) XRD analysis of the fractured surface of a bond made with 5 μm thick Ni–Al₂O₃ at 600°C for 30 min

small Al₂O₃ peak observed was attributed to a reduction in the formation of particle-rich regions within the joint zones due to grain growth which led to an increase in the ductility.

CONCLUSION

TLP diffusion bonding of particle-reinforced Al6061-MMC was successfully achieved using an electrodeposited Ni–Al₂O₃ coating. The bonding process was characterized in four distinct stages: the first stage was solid-state diffusion, which resulted in the formation of three reaction layers promoted by the diffusion of nickel into the aluminum base metal.

The second stage of the joining process was melting and base metal dissolution at the bonding temperature. In this stage, the reaction layers melted to form a liquid phase, followed by dissolution of the base metal as the liquid spreads between the components to be joined through capillary action. The final stage of bonding is isothermal solidification at the bonding temperature in which interdiffusion of Ni into Al results in a change in the composition of the liquid phase leading to solidification. Holding the materials at the bonding temperature resulted in the homogenization of the joint region.

Compositional analysis of the joint region confirmed the formation of eutectic liquid as well as several Al–Ni intermetallic compounds. Additionally, particle segregation was observed at bonding time between 1 and 5 min and decreased as the bonding time increased. The variation of the compounds across the joint region was assessed using microhardness measurements. At bonding times of 1–5 min, hardness values of 150 and 160 VHN were recorded in the joint center, which confirms the segregation of micro-Al₂O₃ particles to the joint interface. The

effect of grain growth resulted in a reduction of the hardness number at 10 min; however, as volume of intermetallic formation increased with increasing bonding time, the hardness increased to a maximum value of 162 at 30 min bonding time.

Shear strength measurements indicated that the strength of the joint rapidly increased to 136 MPa at 10 min bonding time. Further increase in bonding time only resulted in a marginal increase of bond strength. XRD analysis of the joint confirmed the formation of intermetallic compounds such as AlFe₆Si and Ni₃Si within the joint region with increasing bonding time.

Nodular Silicon Al–(12–30)% Si Alloys: Microstructure, Mechanical Properties and Fracture Behaviors

Ruyao Wang and Wei Hua Lu

*Institute of Materials Science and Engineering, Donghua University Yan'anlu Campus,
1882 Yan'an Rd, Shanghai, 200051, China*

Abstract

The microstructure, mechanical properties, and fracture of nodular silicon hypereutectic Al–Si alloys containing 12–30 wt% Si are discussed. The eutectic and primary silicon particles are nodulized, offering an average aspect ratio of 1.60–1.70 with a designed modification practice followed by a solution heat treatment of 8–10 h at 510°C–520°C. Such a soaking temperature does not result in coarsening or clustering of the silicon particles. Nodulization of silicon phase leads to an increase in the tensile strength and ductility of alloys at room and elevated temperatures compared with commercial Al–Si alloys. Increasing the Si content leads the tensile strength and elongation of alloys at room temperature to fall down due to the formation of coarsen primary Si grains, but the ultimate tensile strength at 300°C remains unchanged. The ultimate tensile strength $\sigma_{b-\text{alloy}}$ of hypereutectic Al–Si alloys is inversely proportional to square root of maximum silicon size d_{max} . The initiation and propagation of the crack with continuous increase in applied loading were observed under scanning electron microscope. The fracture surfaces in nodular silicon Al–Si alloys are composed of equiaxed ductile dimples. The finite-element method has been used to study the stress distribution within the different morphologies of Si grain and how Si and Al phases interact during loading.

Keywords: Eutectic silicon sphere; Hypereutectic Al–Si alloy; Nodular silicon; Primary silicon nodule.

INTRODUCTION

Hypereutectic Al–Si alloy is an in situ particulate-reinforced metal matrix composite (MMC). Silicon phase possessing high Young's modulus, hardness, and strength acts as the reinforcement for Al–Si alloys. The presence of hard primary silicon crystals in the eutectic matrix offers a higher wear resistance, which makes the alloys very attractive for castings of automotive engine blocks and head, piston, cylinder lines, and other brake system components. As a general rule of thumb, when the silicon content increases, the wear resistance improves, and the expansion coefficient decreases, and the hypereutectic alloys usually have coarse and angular primary silicon particles, which degrade mechanical properties, generate poor machinability, and limits their industrial usage. Therefore, these alloys have to be modified to change the angular primary silicon crystals into crystals having small and nodular morphology. In 1926, Gwyer and Philips first observed the small silicon nodules in Al–16.6wt%Si–0.5wt%Fe alloy when it is treated with 5%NaOH and then poured into a metal mold at 750°C.^[1] One year later, Gayler reported that when the silicon content was increased to 17.52% in hypereutectic alloy containing 0.027%Na, in the top of the ingot with 1" diameter and 1.25" length a few nodular silicon crystals

also could be found as shown in Fig. 1.^[2] However, at the beginning of the last century, aluminum alloys had not been widely used in industry, and no attention had been paid to this interesting discovery. In 1948, Morrogh and Williams reported the cerium treatment of gray cast iron to produce a spherulitic graphite structure, greatly enhancing the toughness and strength.^[3] It would be expected that the superiority could be achieved in hypereutectic Al–Si alloys, if the morphology of primary silicon could be changed from angular shape into nodular. During the past decades, many technologies have been developed to refine and spherulize silicon grains, either eutectic or primary. The most important, used widely in the foundry, is impurity modification, that is, adding elements or compounds, individually or in combination, to the molten alloy. Most interesting research is the morphological transition in primary silicon reported by Mascré in 1953.^[4] He found that the primary silicon in hypereutectic alloys could be made dendritical or roughly spherical in chill casting by adding a gross excess of sodium in the range of 0.05%–0.1% to the melt, whereas the eutectic was modified to very fine structure. However, the resultant microstructure was defective with high levels of porosity. Adding trace amounts of phosphorus to the melt is a powerful technology to refine the primary silicon particles, but doesn't nodulize the silicon phase, primary or

Fig. 1 Silicon nodule in hypereutectic Al–15.86wt%Si alloy treated with Na^[2]

eutectic.^[5–7] Other different impurities such as strontium^[8–10] and boron^[11] and rare earth elements^[12–14] have also been investigated to modify the morphology of primary silicon particles. Strontium and boron can refine the primary silicon particles in different degrees, depending on the amount of additives. However, those treatments don't lead to the change in primary silicon contour. Rare earth elements (e.g., cerium and lanthanum) and mischmetal are capable of modifying the eutectic silicon and refining the primary silicon in Al–Si alloys, but none of them nodulize the primary silicon.^[12–14] Further studies demonstrated that combined addition of different elements enhances the change in the morphologies of the silicon phase. The combined addition of sodium–strontium can result in a great number of spheroidal silicon crystals than achieved by adding sodium alone.^[15] The addition of strontium in higher amount of 0.1% to phosphorus-treated Al–17wt%Si alloy can cause a dendritic shape of primary silicon in chill casting, thereby improving the mechanical properties.^[9] The combined addition of either phosphorus–cerium^[7] or phosphorus–mischmetal^[16,17] significantly reduced the size of the blocky primary silicon as in commercial phosphorus-treated alloys, with a partially modified eutectic. It is worth noting that the change in silicon morphology is relevant to the mischmetal content, for example, adding 0.6% to phosphorus-treated Al–20wt%Si casting alloy causes a bluntness of the primary silicon crystals in some degree, but the nodular shape can't be achieved. Thus, the achievement of both primary and eutectic nodular silicon in the as-cast state by adding impurities to the molten alloy has remained an elusive goal for foundryman. Quenching modification achieved by chill casting^[18,19] and droplet levitation^[20] is a powerful tool to spheroidize silicon, either primary or eutectic, because an increase in undercooling occurs during solidification of the alloy. As undercooling reaches 73°C or more, primary silicon transforms from faceted shape into nodular.^[21] A highly undercooled melt is the major barrier preventing its application in sand castings and large casting in other casting

methods. The other way to change the morphology of a silicon particle is to heat the alloy at sufficiently high temperature for a long time, for example, at 540°C–545°C for 8–24 h, by which the silicon precipitate in eutectic Al–Si alloy becomes spherical, greatly improving the ductility and fatigue resistance of alloys.^[22–24] In 1964, Kolobnev at Soviet Academy of Science of former USSR showed a microstructure in which the primary silicon in hypereutectic Al–Si alloy heat-treated was blunted and nodulized in some degree.^[25] However, the advantage is offset by the occurrence of coarsening and clustering the nodular silicon due to the high soaking temperature. In 2015, Wladyiak and Kozuń used a combination of three methods to refine and nodulize the eutectic and primary silicon precipitations in Al–20wt%Si alloy. First, a given amount of titanium, phosphorus, and boron was added into the melt, then the test pieces of diameter 10 mm diameter or die castings were poured into the metal mold with water mist cooling, and finally, the modified castings were heat treated at 520°C for 4 h. This combined technology leads to the refinement and spheroidization of the silicon phase, eutectic or primary.^[18] Recently, authors have developed a two-step process to nodulize the silicon crystals in both eutectic and hypereutectic Al–Si alloys, i.e., first adding the designed multi-composition master alloys into the melt to refine primary silicon precipitate accompanied with the partially modified eutectic, then heating the modified alloys at 510–520°C to change the morphology of the silicon crystals from flaky or compact to nodular shape.^[26] It is most important that the heating doesn't, if any, lead to the coarsening or clustering of the silicon grains, making it possible to use in industry.

The focus of this article is as follows:

- Microstructural characteristics of the nodular silicon Al–Si alloys.
- The effect of silicon content on the mechanical properties of the alloys at room temperature and at 300°C.
- The influence of silicon crystal size on the mechanical properties of the alloys.
- Fracture mechanism and its relationship with the microstructure.

EXPERIMENTAL PROCEDURE

The compositions of the alloys tested are given in Table 1.

The alloys were melted in 8-kg graphite crucibles in an electric-resistant furnace. Some melts were prepared in 150-kg graphite crucibles under industrial conditions. A small amount of the additives in master alloys consisting of P, B, Ti, and mischmetal (RE) was added to the melts at 150°C above the liquidus of the melt.^[27] Each melt was degassed with N₂ and poured into metallic molds preheated to 350°C to form a casting with the dimension of 22 × 150 × 220 mm, as shown in Fig. 2. To compare the variations of the properties of the nodular silicon

Table 1 Composition (in wt%) of Al–Si alloys tested

Alloy	Si	Cu	Mg	Mn	Fe
Al–12wt%Si	11.8–12.3	1.00–1.05	0.81–1.10	0.33–0.39	0.38–0.48
Al–14wt%Si	13.7–14.3	1.15–1.20	0.50–0.55	0.26–0.32	0.35–0.45
Al–17wt%Si	16.5–17.8	1.05–1.10	0.80–0.90	0.32–0.37	0.35–0.45
Al–21wt%Si	21.0–22.0	1.10–1.20	0.80–0.90	0.28–0.35	0.40–0.45
Al–30wt%Si	28.0–31.0	1.14–1.20	0.80–0.95	0.35–0.45	0.35–0.38

**Fig. 2** Schematic of sample in Y-form, indicating the sites of the bar for mechanical tests

alloys tested, many melts were treated with the Cu–8%P master alloy.

In order to nodulize the silicon precipitates with the best dimensional growth less than 0.02% of the alloys, the following heat treatments were used:

1. Solution treatment at 510°C–520°C followed by water quenching.
2. Aging at 210°C–220°C for 6 h.

The tensile specimens were machined from the sites shown by dotted lines in Fig. 2. The room temperature test samples were 5 mm in diameter and 28 mm long, while the bars for the elevated temperature test were 4 mm in diameter and 20 mm in gauge length. The elongation was accurately measured for the bars tested at both room temperature and 300°C. The tensile test at 300°C was conducted at a standard strain rate of $3.3 \times 10^{-3} \text{ s}^{-1}$ after holding at 300°C for 30 min in order to minimize the effect of the strain rate on the value measured.

A Quantimet Q 920 was used to measure the geometric parameters of the silicon particles. They are the length l , breadth b , aspect ratio l/b , interparticle spacing λ , and the volume fraction of the silicon phase V . All the samples cut from the fracture surface of each tensile specimen were examined using 30 fields containing a total of 1000–2000 silicon particles.

The initiation and propagation of the crack with continuous loading were observed under a JEM-35C scanning electron microscope at the tensile samples of Al–Si alloys with different morphologies of silicon particles as shown in Fig. 3.

**Fig. 3** Schematic of tensile sample for observing the initiation and growth of microcrack. Arrow “a” indicates the site for observation

RESULTS AND ANALYSIS

Microstructure of Al–Si Alloys

Figure 4 shows the as-cast microstructure of the Al–Si alloys tested. The eutectic Al–12wt%Si alloy exhibits partially modified eutectic silicon with primary aluminum dendrite and small primary silicon precipitate (Fig. 4a). As the silicon content increases to 14%, the near-eutectic alloy contains small amounts of the primary aluminum dendrite in addition to the primary silicon crystal and the modified eutectic (Fig. 4b). The hypereutectic Al–21wt%Si alloy solidifies with small angular primary silicon well distributed throughout the partially modified eutectic (Fig. 4c). The variety of structural characteristics is attributed to the compositions, P and RE, of the additives used in the tests. As is well known, phosphorus prompts the fine angular primary silicon to precipitate in hypereutectic alloys.^[6] Rare earth elements added as mischmetal are weak modifiers for eutectic silicon, accompanied with weakly refining the primary silicon.^[12–14] Rare earth elements depress the eutectic temperature in freezing and shift the eutectic concentration to higher silicon, causing the primary aluminum dendrite to form in eutectic and hypereutectic alloys having silicon content less than 17%. In this case, the microstructure is thermodynamically quasi-equilibrium, providing a strong tendency to transform to a stable equilibrium structure upon heating.

When heating at 510°C–520°C for about 1 h, the eutectic fibers in alloys with silicon level ranging from 12% to

Fig. 4 As-cast microstructure of Al-Si alloys tested. (a) Al-12wt%Si alloy.^[27] (b) Al-14wt%Si alloy. (c) Al-21wt%Si alloy^[27] (optical)

21% are mostly broken down into small pieces, then, after further heating for 8–10 h the silicon pieces change into a small sphere. Meanwhile, primary silicon particles are gradually blunted and become rounded as nodules, the size of which is much larger than eutectic as demonstrated in Figs. 5 and 6. The silicon nodules, eutectic or primary, are distributed separately and uniformly throughout the aluminum matrix. Most of the widths of the eutectic nodules are less than 8 μm (Fig. 7a), and the lengths are less than 10 μm (Fig. 7b). The extent of spheroidization expressed by the aspect ratio l/b of the silicon grain mostly ranges between 1.0 and 2.0 (Fig. 7c). It is interesting that the width of the primary silicon grain is nearly the same, varying from 10 to 20 μm (Fig. 8a). And the length of the silicon grain mostly extends from 20 to 40 μm as shown in Fig. 8b. The average aspect ratio ranges between 1.4 and 1.8 (Fig. 8c). It is obvious that the as-cast modified microstructure offers a strong tendency to spheroidization of the silicon phase in hypereutectic alloys. But in Al-30wt%Si alloy, a large amount of the flaky eutectic silicon has not been broken, appearing as the branching feature (Figs. 5e

and 6e), raising the average aspect ratio to 3.5 (Fig. 7c). Moreover, the primary silicon particles remain faceted in some degree with large sizes and aspect ratio (Fig. 8). The average width is approximately 35 μm and the average length is about 60 μm , which are much larger than those in the alloy with silicon content in the range between 12% and 21%. For alloys of higher silicon content, complete nodulization of the silicon phase, either eutectic or primary, is difficult to achieve. Note that with the increase in silicon concentration, the volume fraction of eutectic silicon nodules linearly reduces when compared to the eutectic alloy, meanwhile increasing the primary silicon volume fraction (Fig. 9). The phenomenon is associated with the growth process of the nodules, in which large silicon, either eutectic or primary, grows at the expense of small eutectic grain, causing the number of eutectic nodules to drop down,^[24] therefore the volume percentage of primary silicon increases, and the fraction of eutectic nodule decreases. The higher the silicon content, the stronger the phenomenon becomes as shown in Fig. 9. It is vitally important that increasing the silicon level gradually raises

Fig. 5 The heat-treated microstructure of Al-Si alloys. (a) Al-12wt%Si alloy,^[27] (b) Al-14wt%Si alloy, (c) Al-17wt%Si alloy,^[27] (d) Al-21wt%Si alloy,^[27] (e) Al-30wt%Si alloy^[27] (optical)

Fig. 6 The morphology of the silicon nodules with aluminum matrix etched away. (a) Al-12wt%Si alloy,^[27] (b) Al-14wt%Si alloy, (c) Al-17wt%Si alloy,^[27] (d) Al-21wt%Si alloy,^[27] (e) Al-30wt%Si alloy^[27] (deep etched, SEM)

the maximum size of the silicon nodule as indicated in Fig. 10, which determines the mechanical properties of alloys. We will discuss these problems in detail later.

Generally, the primary silicon in existing alloy containing silicon more than 15% grows coarsened and faceted with angular interfaces and interior porosity. In the current study, the nodulization of silicon precipitations, eutectic or primary, in hypereutectic alloys with silicon content of up to 21% can be obtained. In addition, no microporosity,

if any, has been observed in castings, and the coarsening and clustering of silicon particles have not been found. The reason to nodulize the silicon phase at low temperature (510°C–520°C) is associated with the multi-compositions, P + RE + Ti + B, of the combined additives. As is well known, RE is capable of refining both eutectic and primary silicon,^[12,13] but P only reduces the size of primary silicon.^[6] Ti or B is the effective α -Al grain refiner in Al-Si alloys only. Moreover, it has been reported that neither

Fig. 7 Distribution of width (a), length (b), and aspect ratio (c) of eutectic silicon nodules in eutectic and hypereutectic Al–Si alloys with different silicon contents after heating at 510°C–520°C

combined addition of (P + RE),^[7,17] (P + RE + Ti),^[28] nor (P + B + Ti)^[18] makes the silicon particles nodular at such low temperature as in current studies. On the basis of the experimental data, it would be expected that the combined additives in the present report would be capable of promoting the silicon atom to dissolve in the aluminum matrix at lower temperature and accelerating the diffusion of silicon, making the nodulization of the silicon precipitate much easier. Undoubtedly, there are a lot of works to be done for deeply understanding the mechanism of the nodulization of the silicon phase.

Mechanical Properties

Figs. 11 and 12 describe a variety of ultimate tensile strength and elongation of the nodular silicon Al–Si alloys against the silicon content at room temperature

and 300°C compared to that in existing commercial Al–Si alloys. There is an evident decrease in the ultimate tensile strength and elongation with the increase of Si concentration, although these values for nodular silicon alloys are much greater than those of the commercially existing alloys with the same Si level.^[29,30] The nodular silicon eutectic Al–12wt%Si alloy offers a higher elongation of 2.5%–3.0% accompanied with a tensile strength of 360 MPa at room temperature, higher than that in commercial alloy by 40%.^[29,30] As the silicon level raises to 14%, the tensile strength ranges between 320 and 360 MPa and the elongation isn't less than 2.5%. Then, when silicon content is more than 17%, the mechanical properties are started degrading. The elongation of the nodular silicon Al–17wt%Si alloy can reach 1.5%–2.5% with a tensile strength of 310 MPa, which is 50% higher than the commercial Al–17wt%Si alloy.^[30] And the Al–21wt%Si

Fig. 10 Variety of maximum sizes of primary silicon crystals versus silicon content

Fig. 11 Variety of ultimate tensile strengths of Al-Si alloys against the silicon content at room temperature and 300°C^[27]

Fig. 12 Variety of elongations of Al-Si alloys against the silicon concentration at room temperature and 300°C^[27]

alloy with silicon nodules has an elongation of 0.7%–1.0% with an ultimate tensile strength of 291 MPa, much more than that of phosphorus-treated Al-(20–24)wt%Si alloys.^[31] It would be interesting that the elongation of the Al-30wt%Si alloy tested can reach 0.5% compared to no elongation in common binary Al-30wt%Si alloy,^[29] and the tensile strength is in the range between 220 and 250 MPa, higher than that in existing alloys.^[29,30] The ultimate tensile strength at 300°C also decreases slightly when increasing the silicon content, but it is still on the order of about 100 MPa for all Al-Si alloys tested, which is higher than the existing alloys with the same silicon content.^[29,30] The elongation at 300°C suddenly drops down from 18% to 4% as the silicon level increases from 12% to 30%. The superiority of nodular silicon alloy over the existing alloy is believed to connect with the reduction of the stress concentration in the area close to the blunted ends or ledges of silicon grains in nodular silicon alloys compared to the angular silicon in commercial hypereutectic alloys.^[32] But the reason why the mechanical properties of hypereutectic alloys significantly degrade as silicon concentration exceeds 17%, large silicon nodule occurring in microstructure, is discussed later.

Fracture Surface

The room temperature fracture surface of commercial eutectic Al-Si alloy that sparkles when tilted in light is usually found, by the examination under high magnification, to be composed of cleavage facets and ledges of silicon particles with a small amount of parallel ridges formed in the narrow area of the aluminum matrix between silicon particles, as shown in Fig. 13a. As silicon content increases to 21% in hypereutectic Al-Si alloy, the fracture surface exhibits the cleavage facets or ledges of the coarse primary silicon precipitates in a great degree, and a few plastic deformations

Fig. 13 The tensile fractures of P-treated Al-12wt%Si alloy (a) and Al-21wt%Si alloy (b) at room temperature, and Al-12wt%Si alloy at 300°C (c) (SEM)

can be observed (Fig. 13b). It is typical brittle fracture. However, the tensile fracture surface tested at high temperature (300°C) consists of many small dimples throughout the matrix, accompanying with the cleavage facets of silicon particles. The event is obviously related to the increased ductility of the aluminum matrix as shown in Fig. 13c. In this case, the fracture surface is dull in some degree.

In comparison, the room temperature fracture surface of the nodular silicon eutectic Al-12wt%Si alloy is dull and does not sparkle or change its brightness when tilted back and forth in light. It is composed of rounded dimples uniformly distributed throughout the matrix under high magnification, as shown in Fig. 14a. The ridges, which separate the dimples, are very sharp, indicating that the internal strain between dimples proceeded almost to rupture. At the bottoms of few dimples, the microcracks on the fractured silicon particles or its ledges are obviously found. It is typical ductile fracture. An increase in silicon

up to 17%–21% leads to a significant reduction of the dimple size, as seen in Fig. 14b. As the silicon concentration is increased to 30%, the cleavage facets or ledges of the coarse primary silicon particles appear on the fracture surface. The aluminum matrix between silicon grains undergoes much less, if any, ductile deformation with a few of dimples of small size, as shown in Fig. 14c. These varieties in fracture features are believed to be the direct result of the differences in crack growth with respect to the morphology of the silicon particles, which determines the variety of the stress distribution in silicon particles and aluminum matrix.^[33]

The fracture surface of tensile sample tested at 300°C is far different from that at room temperature. The surface seems to be completely dark as tilted in light. A number of deeply tapered and equiaxed dimples with the small end down are found under high magnification as shown in Fig. 15. On the wall of the dimples, many plastic

Fig. 14 The tensile fractograph of nodular silicon Al-Si alloys at room temperature. (a) Al-12wt%Si, (b) Al-21wt%Si, and (c) Al-30wt%Si alloys (SEM)

Fig. 15 The tensile fractograph of nodular silicon Al–12wt%Si alloys tested at 300°C (SEM)

deformations can be obviously observed. At the bottom of many rounded dimples, the impurity particles can be found. It is typical ductile fracture accompanying with a high elongation as seen in Fig. 12. The cause is related to the rapidly dropping strength of the aluminum matrix at high temperature and its marked increase in ductility.

DISCUSSION

Silicon is a major alloying element in Al–Si alloys. Its Young's modulus or strength is much higher than Al-matrix by about 170% (Table 2). It is expected that the silicon phase acts as the reinforcement for Al–Si alloy to improve the strength and Young's modulus. In the present report, most of the silicon crystal sizes in nodular silicon Al–Si alloys (Figs. 5 and 6) are in the range of 2 and 20 μm with an aspect ratio of 1.3–2.0, which is of the same structural characteristic of ceramic in particle reinforced MMCs.^[34] Hence, the

nodular silicon Al–Si alloys, either eutectic or hypereutectic, are typical particulate-reinforced MMC in situ.

In the recent decades, many studies demonstrated that the reinforcement morphology, size, distribution, and volume fraction play an important role in strengthening the composites.^[34–39] The shear lag theory is often used to analyze the stress distribution in matrix and reinforcement of composites, and predict the strength of composites in terms of reinforcement size, aspect ratio, morphology, and volume fraction.^[40,41] As is well known, the shear lag model is best suited for an aligned fiber composite and tends to give higher estimates for the mechanical properties of a composite, where the aspect ratio of fiber becomes small. Moreover, using this model, only the average fiber stress can be computed.^[35] In order to understand deeply the interaction of the morphology of silicon crystals with the aluminum matrix in Al–Si alloys and the stress distribution inside of both crystals, the finite-element method has been used to obtain the stress distribution within the aggregates and study how two phases interact during loading.^[42]

The Influence of Morphology of Silicon Phase on the Mechanical Behaviors of Al–Si Alloy

In the present study, two patterns were used to analyze the influence of silicon shapes on the stress distribution, as shown in Figs. 16 and 17.^[43] One pattern for Al–13wt%Si alloy is composed of three silicon nodules (Fig. 16). Another model for Al–15wt%Si alloy contains two nodular silicon particles and one plate silicon crystal with blunted tip (Fig. 17). Figures 18 and 19 illustrate the stress distribution in both silicon shapes and Al-matrix in these patterns, respectively. The stress level in Al-matrix is lower than imposed loading of 100 MPa for both patterns, where the stress level in silicon phase is higher than the loading by about 50%. Hence, the loading to fracture the Al-matrix in Al–Si alloys must be higher than that in the Al-matrix without silicon particle, resulting in the increase in the ultimate tensile strength of Al–Si alloys.

The stress distribution in nodular silicon Al–Si alloy is very attractive. The stress level in the Al-matrix only reaches 80 MPa lower than the imposed loading of 100 MPa, meanwhile the stress in silicon nodule is 130 MPa higher than that in Al-matrix by about 60% (Fig. 18). Moreover, with an increase in loading, the stress in the Al-matrix and the silicon phase proportionally increases.^[43] As shown

Table 2 Some properties of silicon and Al-matrix

Materials	Young's modulus (GPa)	Ultimate tensile strength (MPa)	Mineral hardness	Coefficient of thermal expansion ($\times 10^{-6}/^{\circ}\text{C}$)	Poisson ratio
Silicon	190	550–600 ^a	6.5	7.6	0.044
Al-matrix ^b	70	218	2.75	23.6	0.34

^aCalculated from the bending strength of three plate-like specimens made from polycrystalline silicon.

^bCalculated from the tensile test of bar-like specimens made of aluminum alloy containing 12%Si, 1.10%Cu, 0.90%Mg, 0.35%Mn, and 0.40%Fe and T6 heat treated.

Fig. 16 The pattern to compute the stress distribution in alloy is composed of three silicon nodules. The tensile stress in Z-direction is 100 MPa^[43]

Fig. 17 The pattern is composed of two silicon nodules and one plate silicon crystal with l/b of 100/30. The tensile stress in Z-direction is 100 MPa^[43]

in Table 2, the ultimate tensile strength of silicon is much higher than that in the Al-matrix by 170%. Thus, the crack initiates in Al-matrix prior to appearance of crack in silicon, when the stress in the Al-matrix reaches its ultimate strength with increasing applied loading, and crack grows throughout the Al-matrix, rounding the nodular silicon. The inference is evidenced in our observation with SEM on the initiation and growth of microcrack under continuous increase in applied loading as shown in Figs. 20 and 21. As the loading increases, a lot of parallel slip lines abruptly occur in the Al-matrix area near the nodular silicon crystal, and with further increase in loading the microcracks in the form of void appear in this area. Then the microcracks elongate and widen, and finally some adjacent growing microcracks join together to form a coarse crack, which advances around the nodular silicon and propagates in the Al-matrix with much ductile deformation. In this case, a large number of equiaxed dimples uniformly distribute throughout the fracture surface, and the fractured silicon

Fig. 18 Stress distribution on the cross section NN in Fig. 16^[43]

Fig. 19 Stress distribution on the cross section MM in Fig. 17

particle cannot, if any, be observed (Fig. 14a). The high ductility of the Al-matrix offers the Al-Si alloy a higher elongation, but the ultimate tensile strength of silicon can't be achieved. Therefore, the reinforcing effect of silicon becomes weaker, as indicated in Ref.^[40]

As the bar-like silicon exists (Fig. 17), the stress level in the Al-matrix further drops down to 70 MPa, and the stress in nodular silicon slightly rises to 170 MPa, meanwhile the stress in bar-like silicon increasingly reaches to 190 MPa much higher than in the Al-matrix (Fig. 19). The stress in the silicon nodule is obviously much lower than that in the silicon flake. Therefore, the initiation and growth of microcracks in bar-like Al-Si alloy is far different from that in nodular silicon alloy. As the imposed loading increased the parallel microcracks suddenly initiate within silicon bar, and their orientation is perpendicular to the loading direction in high degrees as shown in Fig. 22, then propagate along the Al/Si boundary and in the Al-matrix (Fig. 23). Note that the space of the Al-matrix, where the crack advances, is much smaller than that in nodular silicon Al-Si alloy. In this case, the potential ductility of the aluminum matrix can't be fully developed, reducing the ductility of alloy,^[33,41] but the

Fig. 20 At the tip of the crack some voids appear and join together to form a void-wise crack. Meanwhile a lot of parallel slip lines occur in the Al-matrix adjacent to the tip of the crack. The arrow indicates the loading direction

Fig. 21 The crack advances around the nodular silicon crystals in the Al-matrix in a zig-zag manner

Fig. 22 When loading applied a lot of microcracks suddenly initiate within many bar-like silicon crystals. The arrow indicates the loading direction

Fig. 23 As loading further increased, the microcracks in neighboring flakes join together, forming a large crack, which crosses the fractured silicon flakes, then advances along Al/Si boundary, growing in Al-matrix. The arrow indicates the loading direction

Fig. 24 When loading is applied many microcracks likely occur within silicon flakes. The microcracks in neighboring flakes join together, and then a large crack occurs, advancing along Al/Si boundary, propagating in Al-matrix in commercial Al-15wt%Si alloy. The arrow indicates the loading direction

ultimate strength of silicon can be reached, greatly improving the reinforcing effect of silicon, causing the tensile strength of alloy to rise. Undoubtedly, with an increase in the aspect ratio of reinforcement, the matrix strengthening significantly improves.^[33]

The fracture mechanism of flaky silicon Al-Si alloy is somewhat similar to bar-like alloy. However, the silicon flake always appears in rugged profile with the growth defects, such as irregular ledges and terraces. These defects induce an elastic stress near these irregularities, which is greater than the normal stress calculated neglecting the irregularities by at least three times or much more.^[32] Therefore, a number of microcracks immediately occur at several silicon flakes as the alloy is subjected to the imposed loading much less than that in alloys with bar-like or nodular silicon crystal as shown in Fig. 24, then, the crack joining

the microcracks propagates along the interfacial Al/Si and throughout the narrow area of the Al-matrix between neighboring silicon flakes. Thus, the fracture surface is composed of the cleavage facets and ledges of silicon particles with small amount of parallel ridges of Al-matrix as shown in Fig. 14. In this case, both the potential of ductility of the Al-matrix and strengthening of silicon can't be exploited in great degree, degrading the strength and ductility of alloy.

Effect of Change in Volume Fraction (Concentration) of Silicon Phase

As is well known, the volume fraction of reinforcing phase is an important factor influencing the mechanical properties of composites. With increased volume fraction of reinforcement, the strength and Young's modulus of particulate Al-based composites generally increase.^[44]

Generally speaking, the rule of mixtures can be used to predict the strength or Young's modulus of composite with the change of volume fraction. This inference is correctly proved in hypoeutectic Al–Si alloys, in which with an increase of silicon concentration from 1% to 12%, the volume fraction of eutectic silicon proportionally rises, causing the tensile strength of the alloy to linearly grow, as demonstrated in Fig. 25. For binary nodular silicon Al–Si alloy, the linear relationship can be expressed by the following approach:

$$\sigma_b = 130 + 550\text{Si}\% \quad (1)$$

As eutectic silicon exhibits flaky contour in unmodified Al–Si alloy, another expression (2) can be found to describe this relationship.

$$\sigma_b = 110 + 300\text{Si}\% \quad (2)$$

Fig. 25 Tensile strength against silicon content in binary hypoeutectic Al–Si alloys

The variety of tensile strength is related with the increase in an elastic stress near the growth defect in Si flake degrading particulate-reinforced effect. Obviously, the morphology of Si phase is a powerful factor influencing the strength of alloy. However, no evidence for the effect of the volume fraction of reinforcement on tensile strength of MMC could be found in present work as seen in Fig. 11, although the volume fraction of total silicon linearly increases as silicon level moves up from 12% to 30% (Fig. 9). This leads one to suspect that there are some factors, and their adverse effect on the mechanical properties is much stronger than reinforcement of volume fraction.

Reinforcing Effect in Change of Silicon Crystal Size

The size of reinforcement is an important factor in determining the mechanical properties of particulate MMCs. Clyne and Wither^[41] summarized the experimental results published in literatures, illustrating how strengthening is strongly dependent on reinforcement size for dispersion or precipitation hardened metals and MMCs. In general, with increasing size of reinforcement the reinforcing efficiency becomes weakened. The reinforcing effect in MMCs, in which the size of reinforcements ranges from 1 to 100 μm , is much weaker than that in the dispersion or precipitation hardened alloys with particles having 0.001–0.7 μm size. Moreover, when the reinforcement size is larger than 20 μm , the crack often occurs in the interior of reinforcing particle as loading.^[46] This phenomenon also has been verified in the present report. Microcrack likely initiates in the interior of the coarse primary silicon crystal of size more than 20 μm prior to the formation of crack when loaded (Fig. 26). Thus, the coarse particle acts as a crack in the matrix rather than a reinforcing constituent, significantly degrading the strengthening effect. In this case, the ultimate tensile strength, $\sigma_{b\text{-alloy}}$, is better represented by the following expression (3)^[38]:

$$\sigma_{b\text{-alloy}} = \frac{K_{Ic}}{Y} d^{-\frac{1}{2}} \quad (3)$$

Where K_{Ic} is the fracture toughness of the alloy tested, Y is a function of specimen and crack shape, and d is the maximum size of the silicon grain.

Lewandowski summarized the published data, which investigated the effect of systematic change in reinforcement volume fraction on the resulting fracture toughness of various discontinuous reinforced Al-based composites based on different aluminum alloys including Al–Si alloys. The fracture toughness K_{Ic} drops down rapidly at low volume fraction (e.g., 0%–10%), but relatively smaller losses in toughness accompany high reinforcement level (e.g., 10%–40%).^[47] Okabayashi, Kawamoto, et al. reported that for the hypereutectic Al–Si alloys, the fracture toughness K_{Ic} remains constant with the change

Fig. 26 The large crack initially appears in the interior of coarse silicon nodule with a diameter larger than 20 μm and penetrates into the Al-matrix at the vicinity of silicon particle as loading imposed

in primary silicon volume fraction from 0% to 15%.^[38] Summarizing the experimental data, it could be assumed that K_{Ic} remains approximately constant in hypereutectic Al–Si alloys with silicon content from 12% to 30%. Therefore, the ultimate tensile strength $\sigma_{b\text{-alloy}}$ of hypereutectic Al–Si alloys containing different silicon levels should be inversely proportional to the square root of maximum silicon size d_{max} (see expression (3)).

Authors tried to locate and summarize the data in literatures relative to the ultimate tensile strength in Al–Si alloys containing silicon content in the range from 12% to 50% with various primary silicon sizes.^[29,38] Data showed that with the addition of silicon content, either the average size of the silicon particles in conventional Al–Si alloys or the maximum size of primary silicon in nodular silicon alloys increases (Figs. 10 and 27), and the ultimate tensile strength decreases (Fig. 28). The relationship between the ultimate tensile strength σ_b and the inverse square root of maximum or average diameter of silicon crystal d is confirmed by plots in Fig. 29. In addition, the same relationship can be found in binary Al–17wt%Si alloy, in which the change in primary silicon grain size is caused by the different cooling rates during freezing. Generally, this relationship could be expressed by Eq. 4:

$$\sigma_b = kd^{-1/2} + b \quad (4)$$

where k and b are constants for a given alloy and test specimen. Constant k and b for the binary and polynary Al–Si alloys are listed in Table 3.

Expression (4) is known as the Hall–Petch relationship, which arose from experimental observations and, when

Fig. 27 The relationship between primary silicon crystal size and silicon content in hypereutectic Al–Si alloys

Fig. 28 Tensile strength versus maximum silicon crystal size for hypereutectic Al–Si alloys with different silicon

dislocation pileup is considered as the operative strengthening mechanism, is successfully used to describe the effect of characteristic microstructural dimension on the stress in single-phase polycrystalline materials (e.g., polygonized aluminum or Al–Cu alloys or Al–Mg alloys) and two-phase alloys (e.g., two-phase steel)^[48] Constant k is considered to be a measure of resistance of Al/Si boundary to silicon crystal cracking, depending upon the chemical composition of alloy and structural parameters including silicon crystal size and volume ratio. Adding the alloying elements, such as Cu, Mg, Mn, Zn, Ni, strengthens the Al-matrix, increasing the resistance of the Al/Si boundary to silicon crystal cracking. Thus, constant k is much larger in nodular silicon Al–Si alloys containing alloying elements than that in binary Al–Si alloy (Table 3).

In this relationship, constant b is considered as a frictional stress resisting the motion of gliding dislocations, constant b must be positive. However, our experimental results and observations in other studies^[49] are not in agreement with the statement. The value of constant b might be positive or negative as shown in Table 3. For binary Al–17wt%Si alloy constant b is positive.^[38] Whereas, for nodular Al–Si alloys and other two binary

Fig. 29 Tensile strength as a function of the inverse square root of the maximum or average diameter of silicon phase in hypereutectic Al–Si alloys with different silicon levels and morphologies

Table 3 Constant k and b for Al–Si alloys with different compositions and structures

Alloy	Constant		Remark	Reference
	k (MPa·μm ^{1/2})	b (MPa)		
Al–17wt%Si	438	59.9	Binary alloy with different cooling rating during solidification	[38]
Al–(11.6–50)wt%Si	812	–8.5	Binary alloys with different silicon level.	[29]
Al–(12–20)wt%Si	1105	–28.0		[38]
Al–(12–30)wt%Si–Cu–Mg–Mn	3404	–75.0	Polynary alloy with different silicon level and nodular silicon crystal.	Present study

hypereutectic Al–Si alloys constant b is negative. Our observations demonstrated that constant b is related to constant k in the manner in which increasing the value of constant k leads constant b to reduce, gradually to fall off from positive to negative, as shown in Table 3. This relationship seems to be attributed to an increased number of dislocations on the Al/Si boundary resulting in a negative value of constant b .^[49] Undoubtedly, in order to deeply clarify the physical meaning of constant b , it is in need of further study.

It is interesting that the ultimate tensile strength at 300°C, with increasing silicon content, remains unchanged at around 100 MPa. Obviously, stress doesn't obey the Hall–Petch relationship. It is thought to be related to the temperature, strongly influencing $d^{-1/2}$ relationship.^[48] At elevated temperature, there are two factors affecting the strength of alloy. First and foremost, at high temperature the plasticity of materials greatly increases. Second is the dynamic recovery and recrystallization.^[49] In this study, the test temperature is 300°C higher than recrystallization temperature of Al–Si alloy, which is $1/2 T_m$ (T_m is the melting temperature). During tensile strength test dynamic recrystallization will occur, making alloy much plastic. As a result, the pile-up group of dislocation will be

easily released, reducing the stress concentration in front of barrier such as interphase or grain boundary. In this case, the dislocation pile-up isn't the operative strengthening mechanism; the stress isn't inversely proportional to square root of the size of primary silicon crystal.^[50,51]

Summarizing the factors influencing the strength of Al–Si alloy, it is reasonable to reach a conclusion that nodulization of silicon phase accompanied with refining the primary silicon particle is an efficient way to enhance the mechanical properties in hypereutectic Al–Si alloys.

CONCLUSIONS

1. Nodular eutectic and primary silicon distributed uniformly and separately throughout the aluminum matrix in Al–(12–30)wt%Si alloys can be achieved using a complex addition of P, RE, Ti, and B into the melting followed by heating at 510°C–520°C for 8–10 h.
2. Nodulization of the silicon particles results in the increase in tensile strength and ductility of Al–Si alloys, when compared with the existing commercial modified alloys at room or high temperature.

3. With an increase in silicon content, either the tensile strength or ductility of the nodular silicon Al-(12–30)wt%Si alloys decreases due to the appearance of the coarse primary silicon grains, but the tensile strength at 300°C is not significantly affected.
 4. The ultimate tensile strength at room temperature of hypereutectic Al-Si alloys containing different silicon levels is inversely proportional to the square root of maximum silicon size $d_{\max}$.
 5. Nodulization of the silicon phase accompanied with refining the primary silicon particle is an efficient way to enhance the mechanical properties in hypereutectic Al-Si alloys.

Non-Heat Treatable Al-Alloys: Development of Intermetallic Particles during Solidification and Homogenization

Olaf Engler

Hydro Aluminium, Bonn, Germany

Katrin Kuhnke and Jochen Hasenclever

Abstract

The materials properties of Al-alloys are controlled by the added alloying elements and by the processing conditions through the resulting materials microstructure. An important aspect in the description of the microstructure is the constitution of the material in terms of alloying elements in solid solution and, in turn, volume, size, morphology, and species of second-phase particles. These constitutional characteristics, conveniently summarized as microchemistry, have an impact on physical properties like thermal or electrical conductivity and on mechanical properties including strength and formability of Al-alloys. In the present article, we summarize the phase selection upon solidification and the changes in microchemistry during subsequent homogenization annealing during conventional industrial processing of non-heat-treatable Al wrought alloys.

Keywords: Homogenization; Microchemistry; Precipitation; Solidification; Solutes; Wrought alloys.

INTRODUCTION

Pure aluminum is very soft, and virtually all technical applications of Al require higher strength. Accordingly, almost all practical applications are based on Al-alloys, which contain Fe and Si (which are present in commercial purity Al after smelting) plus additional contents of the most important alloying elements Mg and/or Mn. Sometimes, other alloying elements are added as well, including Cu, Cr, Zn, and Zr. Ti and/or B are often used for grain refinement in direct chill (DC) casting.

Wrought Al-alloys are commonly subdivided into two classes, heat-treatable and non-heat-treatable alloys, depending on their main hardening and strengthening mechanism. Some aluminum alloys, usually those alloyed with Cu, Zn, or Mg in combination with Si, can be significantly strengthened by controlled heating and quenching sequences followed by natural or artificial aging (“precipitation hardening”). Such alloys are called “heat-treatable.” In contrast, the strength of the “non-heat-treatable” alloys is provided either by solid solution hardening or by dispersion hardening of their alloying elements, mainly Fe, Si, and Mn and/or Mg. Additional strengthening can be created by cold working, i.e., deformation that induces strain hardening.

In the most widely accepted naming scheme for wrought Al-alloy according to the Aluminum Association (AA), each alloy is identified by a four-digit number, where the first digit indicates the major alloying element.

- Alloys of the 1xxx series contain essentially pure **aluminum** with a minimum of 99% by weight; the main additions—either impurities from the smelting process or intentionally added alloying elements—are Fe and Si. The 1xxx alloys are strain hardenable and offer excellent formability, corrosion resistance, and thermal and electrical conductivity. Typical applications include foil and strips for packaging, heat exchanger tubing and finstock, cable sheathing, and electrical conductors.
- The 2xxx series is alloyed with **copper**. They can be precipitation hardened to strengths comparable to steel and find wide applications in the aerospace industry.
- The 3xxx series is alloyed with **manganese** (range 1–2 wt%) and can efficiently be work hardened to strength levels in the range of 100–300 MPa. Alloys of this series are moderate in strength, they have good formability and corrosion performance, and they are suitable for anodizing and welding. Applications include packaging, building, and home appliances.
- The 4xxx series is alloyed with **silicon**, which can be added in comparably large quantities (up to 12%) to cause substantial lowering of the melting point. Applications as wrought products are largely limited to brazing alloys, where a melting point less than that of the parent metal is required.
- The 5xxx series is alloyed with **magnesium** (up to 6%), which leads to solute hardening combined with efficient strain hardening to a strength of 200–350 MPa. Alloys

of this series are weldable and show excellent resistance to corrosion in an aggressive atmosphere and seawater. Therefore, typical applications include road transport, marine and offshore as well as chemical and process industries.

- The 6xxx series is alloyed with **magnesium** and **silicon**. They can be precipitation hardened, though not to the high strength levels of 2xxx and 7xxx series alloys. However, since 6xxx series alloys are easy to machine, are weldable, and have better corrosion properties than the high-strength 2xxx and 7xxx series alloys, they find wide applications as sheet and profiles in building, construction, and automotive industries.
- The 7xxx series is alloyed with **zinc** and usually contains Mg and/or Cu. They can be precipitation hardened to the highest strengths of any aluminum alloy (tensile strengths up to 700 MPa) and are used in aerospace and military applications.
- The 8xxx series is alloyed with other elements that are not covered by the other series. Thus, the 8xxx series includes advanced age-hardenable Al-Li alloys for aerospace applications, and also Fe-rich Al-alloys for packaging applications when the Fe-contents exceed 1%.

The initial strength of the non-heat-treatable Al-alloys, usually in the 1xxx, 3xxx, 4xxx, 5xxx, and some 8xxx series, is provided either by solid solution hardening or by dispersion hardening of their alloying elements. Thus, proper control over the final material properties requires a detailed knowledge of the impact of alloy composition and processing parameters on the microstructure of the resulting material and especially its so-called microchemistry, which includes the state of the second-phase particles and alloying elements in solid solution. It is noted that the majority of non-heat-treatable Al wrought alloys are produced by rolling to plate, sheet, strip, or foil, whereas extrusion to profiles is largely limited to heat-treatable alloys. Accordingly, this article focuses on the production of rolled Al-products rather than extruded profiles. Table 1 gives the AA composition ranges of the most important Al sheet alloys used in this work. Note that all compositions are given in mass or weight percent (wt%), if not stated otherwise.

Rolled products made from Al-alloys are produced in two different ways, either starting from a conventional DC cast ingot, which is hot rolled to a strip of about 2–10 mm, or, to a much lesser extent, from a 2–30 mm thick sheet produced by continuous casting routes (twin roll casting or belt casting). Figure 1 illustrates the processing steps of Al sheet products according to the conventional DC route. The alloys are DC cast as large ingots with dimensions up to 600 mm thick, 2 m wide, and 4–10 m in length. The ingots are sawn at both ends and scalped on their (later) rolling surfaces to remove surface segregation layers and impurities from the casting process and achieve better rolling results.

In preparation for the hot rolling, the ingots are preheated to a temperature of up to 600°C. Depending on the temperatures achieved internal stresses are relieved, soluble phases in the material are dissolved, and short-range segregation is reduced by diffusion processes. Constituent phases are spheroidized and partially re-dissolved, while elements in supersaturated solid solution may precipitate in the form of dispersoids. The homogenized ingots are either directly transferred to the hot rolling line or cooled down and later reheated for hot rolling. In modern production lines, the ingots are reversibly rolled on a breakdown mill in a number of passes to a transfer gauge of 25–40 mm, followed by a high-speed multi-stand tandem mill where the slabs are further reduced in a few consecutive passes to a strip at a controlled exit temperature. The resulting hot strip with a thickness between 2 and 10 mm is coiled and allowed to cool before it is cold rolled to its final gauge.

A sheet of non-age hardening Al-alloys is often supplied in the fully soft-annealed condition (temper designation “O”), which is typically produced by annealing for 1–2 h at temperatures around 350°C. This fully soft, i.e., recrystallized, condition stands out by maximum formability. Depending on the required combination of mechanical strength and formability, various strain-hardened tempers (“H1x”) are also used. The fully hard condition (H18 or H19) is usually obtained with cold work equal to or greater than 75% rolling reduction, but combined with limited ductility. Intermediate tempers H16, H14, and H12 are obtained by lower amounts of cold working, usually after an additional annealing step called interannealing. These intermediate tempers show lower strength but greater ductility, often in combination with lower levels of anisotropy in materials properties. As an alternative, the sheets may be strain-hardened beyond the desired property levels and then back-annealed to the required properties, which results in tempers H2x with enhanced ductility, including the rather common “half-hard” temper H24.

As stated earlier, the properties of non-heat-treatable Al-alloys are largely controlled by the solution/precipitation state of the alloying elements, i.e., the materials microchemistry. Accordingly, homogenization plays a central part in controlling the final materials properties.

Because of the very low solubility of Fe in Al, commercial Al-alloys will always comprise large micron-sized, Fe-bearing intermetallic phases. Type, volume, size, and, especially, morphology of these so-called constituent particles have an impact on ductility and formability. Needle-shaped particles result in increased hardness but lead to reduced formability and fatigue resistance. Homogenization practices involving high soaking temperatures prior to hot rolling may lead to changes in morphology and constitution of constituent phases, which may improve downstream materials properties. Moreover, preheating or homogenization annealing will lead to the formation of fine submicron secondary particles usually called dispersoids,

Table 1 Composition range of the most important Al-alloys addressed in this article (in wt%, rest Al)

Fig. 1 Schematic diagram illustrating the typical steps of thermomechanical processing of Al-alloy sheet

which affect both processing and final materials properties of Al-alloys.

As an example, volume fraction and size distribution of the dispersoids are important factors in dispersion strengthening. Furthermore, solute concentrations of alloying elements and, again, size and volume fraction of dispersoids have a strong impact on the recrystallization of Al-alloys, both during and after hot rolling and, especially, during soft annealing at final gauge. Whereas the recrystallized grain size has a relatively small influence on strength of Al-alloys, it largely affects ductility, with finer grain size giving higher ductility. Thus, to achieve a good balance of strength and formability in the final gauge product, recrystallization to a fine, uniform grain structure is required, which is affected by microchemistry. Solute elements inhibit recovery, which generates recrystallization nuclei, thus tending to increase grain size. Dispersoids tend to refine the grain structure in lean Al-alloys by inhibiting grain boundary movement during recrystallization. On the other hand, a high density of very fine dispersoids may interfere with the nucleation of recrystallization, thus leading to very coarse grained structures.

In the present article, we will summarize the phase selection during solidification and the microchemistry changes upon subsequent homogenization of the most important non-heat-treatable Al-alloys of the 1xxx (and 8xxx), 3xxx, 4xxx, and 5xxx series with special focus on the related downstream materials properties.

METHODS OF MICROCHEMISTRY CHARACTERIZATION

Experimental Characterization Methods

For optical metallography, samples are ground and polished according to standard metallographical techniques. The grain structure of Al-alloys is readily revealed by anodic oxidation ("Barker etch") and subsequent investigation under polarized light in an optical microscope. Quantification of size and volume of large constituent phases is usually performed with polished samples with the help of software packages for image analysis to yield quantitative information on length, width, and area fraction of second-phase particles. The composition of large second-phase particles is routinely analyzed by energy-dispersive X-ray spectroscopy (EDS or EDX) in a scanning electron microscope (SEM) or by microprobe analysis. For

investigation of small dispersoid phases forming during homogenization in the optical microscope the samples are etched, e.g., for 1 min in dilute $\text{H}_2\text{SO}_4/\text{HF}$. Note however that this technique merely provides qualitative information on dispersoid density, in that the size of the dispersoids is greatly exaggerated due to the etching applied. Size and density of the dispersoids can be studied in more detail by SEM or transmission electron microscopy (TEM).

Thermal analysis by differential scanning calorimetry is commonly conducted to determine liquidus and solidus temperatures and may provide information on precipitation and dissolution of second-phase particles. Measurements of the specific electrical resistivity (or conductivity) yield information on the amount of solute elements in the Al-matrix. According to Matthiessen's rule the resistivity, ρ , of an alloy is composed of the temperature-dependent term ρ_0 plus the temperature-independent contribution of elements i in solid solution. Thus, the specific electrical resistivity ρ depends on temperature, T , and the concentration of solute atoms, c_i^{ss} , which can be given as follows:

$$\rho(T, c_i^{\text{ss}}) = \rho_0(T) + \sum_i \alpha_i c_i^{\text{ss}} \quad (1)$$

where α_i are the specific resistivity coefficients for the various alloying elements.^[1]

In addition to measurements of the electrical resistivity, solute atoms can also be traced by measurements of the thermoelectric power (TEP), which is the thermoelectric voltage in response to a temperature difference across the material (Seebeck effect). For analysis of solute elements in Al-alloys, a constant temperature gradient of typically $\Delta T = 10$ K is applied to the sample of interest; the resulting thermo-voltage ΔV is then a measure for the amount of alloying elements in solid solution.^[2–4]

Simulation-Based Methods

For the calculation of the equilibrium state as a function of temperature, the CALPHAD approach is employed (CALculation of PHase Diagrams.^[5] For aluminum alloys, many of the required data have been determined in the European research program COST 507 and published in a thermodynamic database.^[6] In the present study, we use the commercial software package FactSage by GTT-Technologies (Herzogenrath, Germany)^[7] together with an extended database with a special focus on the aluminum-rich corner, including the 14 most important alloying

elements of wrought Al-alloys (B, C, Cr, Cu, Fe, Mg, Mn, Ni, Si, Sr, Ti, V, Zn, Zr), which is distributed by Thermo-Tech Ltd., UK.^[8] The results may either be presented as the classical phase diagram with temperature as a function of the alloy concentration or in the form of the volume fraction of the arising phases as a function of temperature. In technical multi-component Al-alloys, the phase diagrams are usually presented in dependence on the concentration of a given important alloy element, while the other alloying elements are kept constant. Furthermore, CALPHAD simulations can be utilized to get information on the phase composition of nonstoichiometric phases, e.g., α -Al(Fe,Mn)Si.

However, because of the quite high cooling rates of the order of 1 K/s prevailing during industrial DC-casting, the conditions for equilibrium are not usually fulfilled. Accordingly, the as-cast ingots usually comprise an appreciable supersaturation of slow-diffusing species, most notably, Mn and Fe. Following the method going back to Scheil,^[9] the resulting supersaturated particle state can be estimated through a solidification simulation where any diffusion in the solid state is frozen.

Further references on the metallurgy of Al and its alloys, phase diagrams as well as advanced simulation methods regarding microchemistry changes during homogenization annealing may be found in the general bibliography.

DEVELOPMENT OF INTERMETALLIC PARTICLES DURING SOLIDIFICATION AND HOMOGENIZATION OF NON-HEAT-TREATABLE AL-ALLOYS

Al-Fe-Si Alloys (AA 1xxx, AA 4xxx, AA 8xxx)

Introduction

Aluminum of commercial purity always contains additions of Fe and Si, either as impurities or intentionally added as alloying elements. Fe results in a slight increase of strength and better creep characteristics at moderately elevated temperatures, for example, for electrical conductors; Si leads to changes in type and morphology of the constituent phases and hence improves ductility. Because of the low level of alloying elements, 1xxx series alloys generally have very low strength but very high formability and workability together with superior corrosion resistance. The low level of intermetallic particles also makes these alloys very good for anodizing and allow for highly reflective and decorative surface finish and provide high thermal and electrical conductivities. The combination of these properties makes these alloys very suitable for packaging, electronic devices, heating equipment, lighting applications, and decoration.

Thus, in the fully soft-annealed condition (O-temper), commercial purity Al-alloys of the AA 1xxx

series, including the well-known variants AA 1050 and AA 1200, have rather low strength.^[10–14] Higher strength—to allow for down-gauging, for example—may be achieved through increased levels of Fe, for instance, in the 8xxx series alloys such as AA 8079 containing 0.7%–1.3% Fe (Table 1).

In the conventional industrial route, production of Al strip or foil starts with a DC casting operation. Figure 2 shows an example of the microstructure in a DC-cast ingot of alloy AA 1050 after solidification. The microstructure is characterized by a coarse globulitic grain structure containing large eutectic phases, which form the boundaries of the solidified cell structure (e.g., Fig. 2a). The grain size of the alloy was about 300 μm , and the mean cell size was about 40–50 μm . Analysis at higher magnification reveals that the cell boundaries are formed by large (10–50 μm), irregularly shaped second-phase particles (Fig. 2b). It is noted that the grain size can be controlled by the addition of AlTiB grain refiners. The cell size, on the other hand, is largely defined by the cooling rate after solidification, with

Fig. 2 Microstructure of a DC-cast ingot of alloy AA 1050, showing (a) a globulitic grain structure (anodically oxidized) and (b) constituent phases along the cell and grain boundaries (polished)

larger cooling rates resulting in finer cell sizes and smaller eutectic phases. Upon DC casting of large rolling slabs little can be done to change the cooling rate as it is a function of the ingot size and the thermal conditions upon casting. The cooling rate decreases from surface to center as the thermal diffusion path from the water spray increases. This gives rise to slight variations in microstructure from the surface to the center of an as-cast slab.

Phases in Al-Fe-Si Alloys

Figure 3a shows the Al-rich corner of the ternary phase diagram of Al-Fe-Si as a function of the Fe content, computed for an Si content of 0.1%, which is often found in commercial purity Al 1xxx and 8xxx series alloys with higher Fe-contents, e.g., AA 8079 and AA 8021B. The equilibrium phase diagram displays a total of three species of second-phase particles in equilibrium with the Al-matrix (Al), where the stability ranges of which depend on temperature and the exact alloy composition. The maximum solubility of Fe in Al is very low, namely a maximum of 0.05% at 650°C and 0.03% at 600°C.^[15] Accordingly, alloys based on commercial purity Al will always comprise Fe-bearing constituent phases. Alloys with low Si content usually contain rather large fractions of the monoclinic phase Al_3Fe (or $\text{Al}_{13}\text{Fe}_4$). This phase usually forms needlelike particles that adversely affect formability of Al-foil alloys.^[16]

Because of the quite high cooling rates prevailing during industrial DC-casting, the conditions for equilibrium are not fulfilled in practice; accordingly, the as-cast ingot will be supersaturated by Fe.^[17–20] Under these conditions, besides the stable monoclinic Al_3Fe phase, there is a metastable phase Al_6Fe . This phase is isomorphous to the orthorhombic Al_6Mn phase, which is regularly encountered in Mn-containing alloys, e.g., in 3xxx or 5xxx series alloys (see later). Furthermore, the literature describes

other metastable phases of Al_mFe , where m varies from 4 to 5.^[16–19] Homogenization at high temperatures leads to a transformation of the metastable Fe-bearing phases toward stable Al_3Fe .^[21–23]

Al-alloys with increased Si content exceeding 0.5% display significant portions of ternary AlFeSi phases (Fig. 3b).^[15–19,24] At medium Si contents and/or high temperatures, the cubic α - AlFeSi phase is obtained. The chemical composition of this phase shows rather large scatter and is described as $\text{Al}_8\text{Fe}_2\text{Si}$ or $\text{Al}_{12}\text{Fe}_3\text{Si}$. That is to say, the ratio of Fe:Si (in at. %) may vary between 2:1 and 3:1 or, in wt%, between 4:1 and 6:1. Increased Si contents and lower temperatures tend to stabilize the monoclinic phase β - AlFeSi . For this phase, a stoichiometric composition of Al_5FeSi is reported; thus, the Fe:Si ratio (in at. %) is approximately unity. This ratio expressed in wt% is very close to 2:1.

Microchemistry Evolution in Typical Low-Si Packaging Alloys

The typical Al-foil alloys have low Si contents of the order of 0.1%–0.2% and are differentiated mainly by their Fe-contents, ranging from AA 1050 with typically 0.35% Fe up to AA 8021B with more than 1.5% Fe (Table 1). Accordingly, the microstructure after solidification is composed of large needlelike Fe-bearing particles (Fig. 2b), either metastable particles of type Al_6Fe or Al_mFe or stable Al_3Fe particles. The volume of these constituent particles depends on the specific Fe content. During homogenization annealing, volume, size, and shape of the Al_3Fe constituents remain largely unchanged; only at high soaking temperatures exceeding 550°C will very limited coarsening and spheroidization of the Al_3Fe constituents possibly occur. As already stated, simultaneously the metastable Al_6Fe or Al_mFe particles are gradually transformed into stable Al_3Fe .^[21–23]

Fig. 3 Al-rich corner of the ternary phase diagram of Al-Fe-Si, (a) computed for 0.1% Si, (b) computed for 1.0% Fe (FactSage)

Furthermore, homogenization is accompanied by formation of dispersoids, whose volume depends on the Si content and the soaking temperature. Figure 4 shows an example for alloy AA 8079 with about 1% Fe, which is the most widely used alloy for Al foil. Evidently, homogenization annealing for 1 h at 500°C led to the formation of small particles with average sizes below 100 nm with either platelike or needlelike morphology (Fig. 4a). EDS analysis in the TEM proved that, independent of their morphology, these particles are mainly Al_3Fe phases; only at low soaking temperatures, occasionally $\alpha\text{-AlFeSi}$ dispersoids were observed.^[25–27] At longer homogenization times, the ratio was shifted toward the needlelike particles; simultaneously, the particles coarsened slightly to an average size of some 100 nm combined with a reduction in density. Particle coarsening upon homogenization annealing becomes evident from the dispersoids' size distribution function presented in Fig. 4b. At a homogenization temperature of 550°C, the coarsening reactions were amplified; the mean size of the dispersoids increased to 150–200 nm. At 600°C, the fraction of dispersoids was very low, only occasionally small compact dispersoids were observed.

Fig. 4 TEM-analysis of the dispersoids forming in alloy AA 8079 (a) dispersoids observed after annealing for 1 h at 500°C, (b) size distribution of dispersoids after various homogenization treatments^[27]

It is seen that the phase diagrams of the typical Al-foil alloys, ranging from AA 1050 with typically 0.35% Fe up to AA 8021B with more than 1.5% Fe, resemble each other, in that the microchemistry is composed of Al_3Fe particles and, at low temperatures, some $\alpha\text{-AlFeSi}$ phases (Fig. 3a). Interestingly, the volume of the Al_3Fe constituents scales with the Fe content, yet the concentration of Fe has no impact on their size. To illustrate this, Fig. 5 shows two micrographs of soft-annealed 45 μm Al-foil from alloys AA 1050 and AA 8021B, showing a significant increase in volume but no difference in size of the large constituent particles.^[28] This is the reason that foil alloys with as much as 1.5% Fe can readily be cold rolled to thicknesses below 10 μm . Thus, an increase in Fe leads to a significant reduction in final grain size and, in turn, improvement in both materials strength and formability of Al-foil.

Alloy AA 8011 with Increased Si Content

Al-alloys with increased Si content exceeding 0.5% display significant portions of ternary AlFeSi phases. At medium Si contents and/or high temperatures, cubic $\alpha\text{-AlFeSi}$ is observed, whereas at further increased Si contents and lower temperatures, monoclinic $\beta\text{-AlFeSi}$ prevails.^[15–19,24] Accordingly, in alloy AA 8011 with a balanced Fe and Si content of the order of 0.8%, two types of constituent phases were reported in the as-cast state (Fig. 6), including $\alpha\text{-AlFeSi}$ particles with a characteristic “Chinese script” morphology (Fig. 6b) and needlelike Al_3Fe phases (Fig. 6c).^[27] Homogenization annealing of alloy AA 8011 has a larger impact on the constituent particles than observed in the low-Si alloys described earlier.

Fig. 5 Microstructure in soft 45 μm foil made from (a) AA 1050 and (b) AA 8021B, showing significant increase in particle volume (longitudinal section, optical microscopy)^[28]

Fig. 6 Optical micrographs of alloy AA 8011 in the as-cast state, showing two types of constituent phases (polished)^[27]

In alloy AA 8011, with increasing soaking temperature, both the needlelike Al_3Fe phases and the “Chinese script” $\alpha\text{-AlFeSi}$ phases started to fragment into smaller particles. At higher temperatures, most notably at 600°C , significant coarsening of the phases combined with a decreasing aspect ratio occurred (Fig. 7a). At all times and temperatures the majority of these phases can be classified as $\alpha\text{-AlFeSi}$ with an Fe:Si ratio of about 3.5, whereas the fraction of Al_3Fe particles was notably lower than in the as-cast condition. In samples annealed at 500°C , a significant portion of $\beta\text{-AlFeSi}$ particles with an Fe:Si ratio of below 2:1 was observed (red squares in Fig. 7b). In the samples annealed at 550°C , merely a few $\beta\text{-AlFeSi}$ particles were obtained (filled blue circles), whereas after annealing at 600°C all $\beta\text{-AlFeSi}$ particles had vanished (open blue circles and green triangles). These observations imply that during slow heating up to temperatures of 500°C Al_3Fe is transformed to $\beta\text{-AlFeSi}$, which, at higher temperatures, is further transformed to $\alpha\text{-AlFeSi}$ (e.g.,).^[29] This behavior is in accordance with results reported for 6xxx series alloys with high Si concentration,^[30,31] while in 1xxx series alloys with lower Fe and Si contents, an $\alpha\text{-AlFeSi} \rightarrow \text{Al}_3\text{Fe}$ phase transformation prevails.^[22,32,33] Thus, homogenization annealing of alloy AA 8011 leads to a spheroidization of the $\alpha\text{-AlFeSi}$ constituents, whereas the Al_3Fe particles are transformed via $\beta\text{-AlFeSi}$ to $\alpha\text{-AlFeSi}$. This phase transformation with the concomitant changes in morphology is probably responsible for the improved formability and ductility of alloy AA 8011.^[11,34]

In the Si-bearing alloy AA 8011, merely one type of dispersoids was observed, viz., platelike $\alpha\text{-AlFeSi}$ particles with sizes of around 100 nm .^[27] Unlike in alloy AA

Fig. 7 (a) Optical micrograph of AA 8011 after homogenization for 5 h at 600°C , showing significant changes in the morphology of constituent phases (polished); (b) composition of the constituent phases in the as-cast state and after various homogenization annealings, presented in the form of their Fe and Si contents (microprobe)^[27]

8079, size and aspect ratio of the dispersoids in AA 8011 change only little with soaking time and temperature. It is noted that small additions of a few tenths of a percent of Mn already lead to the formation of the isostructural quaternary $\alpha\text{-Al(Fe,Mn)Si}$ phase (see later). Higher Mn-contents up to 0.5% cause considerable solid solution hardening, leading to a noticeable increase in the strength of Mn-bearing AA 8xxx alloys like AA 8006 and AA 8014 (Table 1).^[11,12,35,36]

AA 4xxx Series Alloys

In principle, Si can be added in comparably large quantities (up to 12%) to cause substantial lowering of the melting point without producing brittleness in the resulting alloys. Al-Si alloys containing high levels of Si are widely used

in the foundry industry due to their high fluidity during casting and also because Si reduces the shrinkage during freezing and the coefficient of thermal expansion of the cast product. However, since high levels of Si reduce the ductility, alloys with Si contents in excess of 1% find only a limited number of applications as wrought product, for example, as a brazing sheet where alloys with Si contents in the range 7%–11% are employed (Table 1). Because of their low melting point and good flow characteristics, such AA 4xxx series alloys are well suited as a braze layer, which is clad on a core made of an alloy with a higher melting point, typically an AA 3xxx series alloy (see Section “Al-Mn-Fe-Si Alloys (AA 3xxx)”). In the high-Si AA 4xxx alloys eutectic Si becomes the most prominent second phase besides some β -AlFeSi (Fig. 3b). Indeed, for the eutectic composition of 12.5% Si, pure eutectic microstructures are obtained; whereas hypo-eutectic alloys with 7%–11% comprise mixed microstructures consisting of Al-rich dendrites and a large volume of Al/Si eutectic phase (Fig. 8).

Al-Mn-Fe-Si Alloys (AA 3xxx)

Introduction

AA 3xxx series alloys are important commercial Al-alloys containing Mn as main alloying element (range 0.5%–1.5%) together with additions of Fe and Si. Mn renders the alloy ductile; in combination with Fe, it improves the castability of the alloy and reduces shrinkage during metal solidification. Mn increases strength and hardness by a combination of solid solution hardening and, mainly, dispersoid hardening due to the formation of Mn-rich dispersoids. AA 3xxx alloys have moderate mechanical strength and high ductility, resulting in good formability, while still allowing a wide range of mechanical properties through various strain hardened tempers. In many of the AA 3xxx alloys, additions of Cu up to 0.3% increase the materials strength, e.g., in AA 3003 (Table 1). In several AA 3xxx alloys, the strengthening effect of Cu is replaced or supplemented by additional additions of up to 1% of Mg, which offers further solid solution strengthening (e.g., AA 3104 and AA 3105). Because of the favorable combination of strength and formability, weldability, anodizing behavior, and corrosion performance, AA 3xxx alloys find widespread application in packaging, building, and home appliances. The most prominent application of AA 3xxx series alloys is the body of beverage cans due to the alloys' good formability by pressing, roll forming, and drawing.^[37,38] Further applications include heating equipment, such as brazing sheet and heating tubes, where AA 3xxx series alloys perform well with their relatively high thermal conductivity combined with medium strength and good corrosion resistance.^[39]

Phases in Al-Mn-Fe-Si Alloys

At 650°C, Al can solve up to as much as 2% of Mn, but at lower temperatures the solubility rapidly drops. Addition of alloying elements such as Fe and Si decreases the Mn solubility in Al. Accordingly, the phase diagram reveals existence of several Mn-bearing phases with different Fe and/or Si contents, as shown in Fig. 9a in the form of the Al-rich corner of the quaternary Al-Mn-Fe-Si phase diagram. It is seen that the microstructure of AA 3xxx alloys is controlled by two Mn and Fe bearing phases, viz., Al_6Mn and, at larger Si-concentrations, a quaternary phase denoted as $\alpha\text{-Al(Fe,Mn)Si}$. Note that in the Al_6Mn phase significant portions of the Mn-atoms may be substituted by Fe; therefore, the phase is commonly denoted as $\text{Al}_6(\text{Mn,Fe})$.^[40,41] The quaternary α -phase is usually described as cubic α -phase with the composition $\text{Al}_{15}(\text{Fe,Mn})_3\text{Si}_2$ or $\text{Al}_{12}(\text{Fe,Mn})_3\text{Si}$,^[41–43] though the exact composition may vary to a large extent. Small additions of Cu will contribute to solid solution strengthening, but have only little influence on the microstructure and phases of AA 3xxx alloys. Additions of Mg up to 1% lead to the formation

Fig. 9 FactSage thermodynamic simulations for AA 3xxx series alloys, showing (a) Al-rich corner of the quaternary phase diagram of Al-Mn-Fe-Si, computed for 1.0% Mn and 0.5% Fe, (b) Scheil solidification simulation for alloy AA 3103 with 1.0% Mn and 0.5% Fe as a function of the Si content

of Mg_2Si phases and, as such, will affect microchemistry evolution. This will be discussed at the end of this section.

Because of the nonequilibrium cooling rates during industrial DC casting, the Al-matrix in as-cast ingots of the 3xxx series will appreciably be supersaturated with the slow-diffusing species Mn and Fe. As mentioned earlier, the resultant particle state can be estimated through a solidification simulation, where any diffusion in the solid state is frozen.^[9] Figure 9b shows the results of such so-called Scheil simulations for an alloy AA 3103 with 1.0% Mn, 0.5% Fe, and two different Si contents, viz., 0.15% and 0.5% Si, presented in the form of the volume fraction of the arising phases as a function of temperature. The Scheil simulations confirm that during solidification two types of constituent particles may form, viz., the Si-free $\text{Al}_6(\text{Mn,Fe})$ phase as well as the Si-bearing $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ phase, the ratio of which being controlled by the alloy's Si content. Thus, the as-cast microstructure of AA 3xxx is typically comprised of a fairly large volume of these two eutectic phases, with the volume and ratio of the two depending on the exact alloy composition, most notably its Si content and cooling conditions.

Microchemistry Evolution in Alloy AA 3103

In what follows, we will describe the phases forming upon solidification and subsequent homogenization for alloy AA 3103 with 1.0% Mn, 0.5% Fe, and 0.15% Si as a reference case. Figure 10 shows several optical micrographs along a typical two-stage homogenization cycle of such high-Mn alloys. In this alloy with low Si, most constituents are of the $\text{Al}_6(\text{Mn,Fe})$ phase. It is seen that during heating particle break-up due to spheroidization and coarsening

Fig. 10 Evolution of microstructure and electrical conductivity, σ , during two-stage homogenization of alloy AA 3103 (optical microscopy, etched)

of the eutectic particles occur.^[44] Thus, size and volume fraction of the constituents increase, whereas their aspect ratio decreases during homogenization. Moreover, the Mn:Fe ratio of the $\text{Al}_6(\text{Mn,Fe})$ constituents increases during homogenization.^[45] These coarsening reactions are obviously controlled by the precipitation of Mn from the supersaturated matrix.

Simultaneously, formation of dispersoids is observed during heating up to soaking temperature. The majority of these dispersoids are of the Si-rich $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ phase. The micrographs and the evolution of electrical conductivity σ included in Fig. 10 clearly show that there is a maximum

in dispersoids density at around 500°C.^[45] At higher temperatures, the dispersoids are increasingly re-dissolved, which is apparent from the decrease in electrical conductivity between 500°C and 600°C. During holding at 600°C, the electrical conductivity starts to increase again, implying renewed precipitation of Mn-bearing phases. Evidently, two reactions have to be discerned, (i) growth of the pre-existing $\text{Al}_6(\text{Mn,Fe})$ constituents and (ii) formation of rather coarse $\alpha\text{-Al(Fe,Mn)Si}$ particles as visible in Fig. 10.^[46,47] During reduction of the homogenization temperature to the sub-homogenization temperature of 500°C, the density of these rather coarse dispersoids increases noticeably, which is also evident from the renewed increase in electrical conductivity. In industrial practice, such two-stage homogenization cycles are aimed at improving recrystallization kinetics by producing a dedicated microstructure with a large density of fairly coarse dispersoids.

During the heat treatment a phase transformation from $\text{Al}_6(\text{Mn,Fe})$ particles to $\alpha\text{-Al(Fe,Mn)Si}$ occurs, in that the fraction of $\alpha\text{-Al(Fe,Mn)Si}$ increases with temperature and homogenization time.^[44,48] Apparently, this phase transformation from $\text{Al}_6(\text{Mn,Fe})$ to $\alpha\text{-Al(Fe,Mn)Si}$ is controlled by diffusion of Si to and incorporation in the original $\text{Al}_6(\text{Mn,Fe})$ constituents. As such, the phase transformation is controlled by the available Si, which depends on the overall alloy composition and the exact time/temperature profile. Figure 11 shows a quantitative analysis of the phase transformation $\text{Al}_6(\text{Mn,Fe})$ to $\alpha\text{-Al(Fe,Mn)Si}$ for an alloy AA 3103 with 0.2% Si.^[44] As will be addressed later, this phase transformation is an important factor upon producing can-body stock.

Brazing Sheet

It is seen that homogenization offers a valuable tool in controlling solute level and dispersoid density, which, in turn, can be used to optimize downstream materials properties.

Fig. 11 Progress of phase transformation from $\text{Al}_6(\text{Mn,Fe})$ to $\alpha\text{-Al(Fe,Mn)Si}$ during heating of alloy AA 3003 (by courtesy of Prof. Y.J. Li, NTNU Trondheim)

The sequence of precipitation and re-dissolution of dispersoids described earlier is utilized upon the production of AA 3xxx sheet for heat exchanger applications. Since the 1970s, most heat exchangers are made from Al-alloys, including radiators, heater cores, oil coolers as well as evaporators and condensers in air-conditioning devices. A typical modern car radiator consists of a brazed core made of different Al-alloys in tubes, end plates, side plates and fins, and a plastic tank on each side.^[39] Brazing of Al is most often performed using sandwich material in which the core alloy—usually an AA 3xxx Al-Mn alloy or, less frequently, a dilute AA 6xxx Al-Mg-Si alloy—is clad with a thin layer of a braze (or filler) with a lower melting point, typically a hypoeutectic AA 4xxx series alloy containing 7%–11% Si. During the brazing process, the clad layer begins to melt during heat-up beyond the Al-Si eutectic temperature of 577°C. The core remains solid and prevents sagging and/or distortion of the heat exchanger assembly. With proper fluxing in a controlled atmosphere brazing (CAB) furnace, the liquidized clad layer establishes a joint upon subsequent cooling and solidification (Fig. 12a).

Fig. 12 (a) Cross section of the joint between a tube and a fin in a brazed car radiator, (b) penetration of Si from the cladding into the core material (by courtesy of Dr. H.-E. Eckström, Sapa Technology)

Thus, in order for the sheet to be brazeable, the solidus temperature of the core material must be higher than that of the filler, i.e., of the order of 600°C. Therefore, brazing sheets are commonly made from alloys of the AA 3xxx series that contain up to 0.5% Fe and 1%–1.5% Mn, which gain mechanical strength by solute and, particularly, by dispersion hardening. The brazing sheet is often supplied with a coarse grained—or rather strongly elongated—grain structure in order to improve sagging resistance upon brazing and to prevent Si from the clad layer to diffuse along the grain boundaries into the core material (Fig. 12b).^[49,50] Loss of Si due to diffusion would give rise to an increase in the melting temperature of the filler material, together with a reduction in its ability to flow and form joints. Furthermore, penetration of Si into the core is detrimental to the corrosion resistance.

The brazing sheet is produced through hot and cold rolling processes. The core alloy is clad with a layer of 5%–10% thickness of the core either on one or on both sides with the filler. The sandwich of as-cast ingot plus—mechanically joined or welded—clad is preheated, with the temperatures involved depending on the demands regarding final grain size.^[50,51] Heating of the ingots to temperatures below 500°C gives a coarse grain size, since finely dispersed precipitates will strongly interfere with the progress of recrystallization during the brazing cycle.^[52] A two-stage homogenization with a soaking temperature of about 600°C, followed by controlled cooling and hot rolling at 500°C will give rise to fairly coarse dispersoids and, consequently, results in a fully recrystallized material with a much smaller grain size.^[52] The homogenized sandwich is then introduced into the rolling mill, where the connection between core and clad material is achieved by roll bonding during the first hot rolling passes. The material is conventionally hot and cold rolled to final gauge, where it may be delivered soft annealed, i.e., in temper O, or back-annealed, e.g., to temper H22, H24, or H26.

Can-Body Stock

The most common Al-alloy for beverage cans is AA 3104, which provides an optimum combination of strength and formability during can production. The alloy contains about 1% of both Mn and Mg. Continuous efforts to increase the strength for further materials savings by down-gauging led to the addition of small amounts of Cu up to about 0.2%. Both Cu and Mg provide increased strength mainly by solid solution hardening. However, Mg affects the intermediate precipitation behavior in AA 3xxx alloys due to the formation of Mg₂Si particles. As stated earlier, DC casting is accompanied by an appreciable supersaturation of the Al-matrix by the main alloying elements, including Si. During subsequent heating up to homogenization temperature, beginning at temperatures around 350°C, the solute Si tends to precipitate with the

solute Mg from the alloy by forming Mg₂Si particles (an example will be shown in the next section). However, at higher temperatures Mg₂Si is not stable in 3xxx alloys. Rather, α -Al(Fe,Mn)Si dispersoids nucleate on the pre-precipitated Mg₂Si particles, leading to their dissolution.^[53,54] At low temperatures, formation of Si-free Al₆(Mn,Fe) dispersoids has been observed as well, which, at increasing temperatures, are successively transformed through diffusion of Si into the final α -Al(Fe,Mn)Si phase.^[55] Other researchers have shown that α -Al(Fe,Mn)Si dispersoids can also nucleate directly on the Al₆(Mn,Fe) constituent particles.^[56]

The common fabrication route for Al can stock consists of DC casting of large ingots, homogenization, breakdown hot rolling followed by tandem hot rolling to about 2–3.5 mm hot strip, and final cold rolling, resulting in the finish gauge sheet with a thickness below 0.3 mm with high strength (greater than 275 MPa, i.e., state H19). An important requirement to control earing at final gauge is to achieve a fully recrystallized microstructure with a pronounced cube texture in the hot strip.^[55,57] This implies that the material may undergo only little recrystallization during hot rolling (so-called “inter-pass recrystallization”), but shows rapid recrystallization during the cooling of the coiled hot strip (so-called “self-annealing”). Dedicated two-stage homogenization practices have been developed to produce a suitable dispersoid structure (Fig. 13a) in order to control recrystallization upon self-annealing of the hot strip.^[38,53,58] Furthermore, suitable homogenization practices for can-body stock entail a certain amount of the phase transformation from Al₆(Mn,Fe) to α -Al(Fe,Mn)Si, see Fig. 13b.^[53,54,58–61] Formation of the—harder— α -Al(Fe,Mn)Si phase facilitates can production by abrading pickup of Al at the ironing tools and hence improves the galling resistance.^[54,59]

Al-Mg-Mn-Fe-Si Alloys (AA 5xxx)

Introduction

5xxx series are alloyed with Mg (up to 6%), often in combination with Mn. Mg leads to solute hardening combined with efficient strain hardening in AA 5xxx series alloys. Thus, AA 5xxx series alloys are generally stronger than the medium strength AA 3xxx alloys, while still having very good formability. These favorable mechanical properties combined with excellent corrosion resistance, the high-quality anodizing ability, and weldability result in many applications for outdoor exposure: in building, scaffolding, and especially marine applications (ship building, platforms, etc.).^[62–64] Also in automotive, 5xxx series alloys are used for press formed body-parts and chassis components due to their good combination of strength and formability.^[39,65] Finally, coil-coated sheet of the alloy AA 5182-H48 is typically used for the ends (lids and tabs) of beverage cans.^[66,67]

Fig. 13 Second-phase particles in AA 3104 can-body stock, (a) TEM bright field, showing dispersoid structure, (b) optical micrograph, showing constituent particles consisting of $\text{Al}_6(\text{Mn,Fe})$ (bright), and $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ (dark) together with several dispersoids in the cell interior (etched in dilute H_3PO_4)^[61]

Phases in AA 5xxx Alloys

Figure 14 shows the Al-rich corner of the phase diagram of Al-Fe-Mn-Si-Mg as a function of Mg concentration, computed for 0.5% Mn, 0.3% Fe, and 0.15% Si. It appears that up to Mg contents of the order of 3%, the microchemistry evolution resembles that of the Mg-containing AA 3xxx alloys like AA 3104. The phase diagram is controlled by two Mn and Fe bearing phases, namely $\text{Al}_6(\text{Mn,Fe})$ and, mainly at high temperatures and low Mg-concentrations, quaternary $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$. With decreasing temperature and, most notably, with increasing Mg-concentrations over 4%, the latter one is replaced by Mg_2Si .

The dominant constituent particles formed during solidification of commercial DC-cast AA 5xxx ingots have been identified to be $\text{Al}_3(\text{Fe,Mn})$, $\text{Al}_6(\text{Mn,Fe})$, $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$, and Mg_2Si , with the exact types of the particles depending

Fig. 14 FactSage thermodynamic simulations for AA 5xxx series alloys, showing the Al-rich corner of the equilibrium phase diagram of Al-Mg-Mn-Fe-Si (computed for 0.5% Mn, 0.3% Fe, 0.15% Si)

on the Fe, Mn, and Si concentration of the alloy.^[68–75] In alloys with high Mg-contents eutectic Al_8Mg_5 particles are also found.^[76,77]

AA 5xxx Alloys with Low Mg

AA 5xxx alloys with low Mg include important structural Al-alloys like AlMg_2 (AA 5251), $\text{AlMg}_{2.5}$ (AA 5052), AlMg_3 (AA 5754), and AlMg_3Mn (AA 5454) (Table 1). These alloys all contain 2.0%–3.5% of Mg together with varying contents of dispersoid-building elements Mn and/or Cr. Kumar et al. investigated the chemical composition of constituent particles in as-cast AA 5754 by microprobe analysis and found Mg_2Si , needle- or platelet-shaped $\text{Al}_3(\text{Fe,Mn})$ particles as well as branched (“Chinese script”) $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ particles.^[73] Engler et al. studied the solidification microstructure of DC-cast AA 5454 with more Mn and obtained $\text{Al}_6(\text{Mn,Fe})$ constituents plus a minority of both $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ and Mg_2Si ; Fig. 15a shows a micrograph where two of these phases can clearly be discerned.^[75] Thus, with an increasing Mn content of the alloy, the constituents shift from $\text{Al}_3(\text{Fe,Mn})$ with a low concentration of Mn to $\text{Al}_6(\text{Mn,Fe})$ containing appreciably higher levels of Mn.

As described earlier for the Mg-containing 3xxx alloys, during heating to homogenization temperature, beginning at around 350°C, the supersaturated Si starts to precipitate with the excess Mg from the alloy by forming Mg_2Si particles. These extra Mg_2Si particles favorably nucleate at pre-existing particles, viz., the Fe- and Mn-bearing constituents. Figure 15b shows an example where Mg_2Si particles with a size of several tenths of a micron had formed at the $\text{Al}_6(\text{Mn,Fe})$ constituents in alloy AA 5454.^[75] However, Mg_2Si is not stable in alloys with medium Mg

Fig. 15 Micrographs of alloy AA 5454: (a) as-cast state, showing two different types of constituent phases (polished), (b) after annealing at 450°C showing nucleation of small Mg_2Si particles at the $Al_6(Mn,Fe)$ constituents^[75]

concentrations around 3% (Fig. 14). Hence, at higher temperatures, the extra Mg_2Si phases are being re-dissolved and, at temperatures greater than 500°C, even the original large Mg_2Si constituents begin to dissolve, leading to a re-increase of Si in solid solution.

Most importantly, homogenization annealing is characterized by heavy precipitation of fine second-phase particles (Fig. 16a,b). The re-dissolution of Mg_2Si phases during heating to temperatures in excess of 500°C with the resulting re-increase of Si in solid solution provides the driving force for the precipitation of fine $\alpha-Al(Fe,Mn)Si$ dispersoids. The semiquantitative EDS spectrum shown in Fig. 16c substantiates that the dispersoids contain significant levels of Mn, Fe, and Si, implying that the dispersoids are of type $\alpha-Al(Fe,Mn)Si$, while the Mg peak most likely

Fig. 16 Analysis of dispersoids in alloy AA 5454 after homogenization for 7 h at 550°C: (a) optical micrograph (etched), (b) TEM-bright field image, and (c) typical EDS spectrum of dispersoids, showing presence of Mn, Fe, and Si^[75]

stems from the surrounding matrix. Note that this behavior is analogous to the formation of $\alpha-Al(Fe,Mn)Si$ dispersoids in Mg-containing alloys of the 3xxx series described above.

Volume and size of the α -dispersoids in AA 5xxx alloys largely depend on the time/temperature cycle of the homogenization practice applied. An increase in soaking temperature is accompanied by an increase in size and mean separation of the dispersoids. A two-stage homogenization practice with a second step at a lower temperature leads to a sharp decrease in supersaturated elements Fe, Mn, and Si and a further increase in size and volume of α -dispersoids. Accordingly, the microchemistry of AA 5xxx alloys can be optimized through suited homogenization practices to control the downstream recrystallization behavior.^[75,78,79] In samples with a large volume of small dispersoids, a large Zener drag retards recrystallization.^[52] Samples homogenized at higher temperature and, especially, with a two-step homogenization practice are characterized by coarser dispersoids and, in turn, lower Zener drag, which facilitates recrystallization.

In conclusion, AA 5xxx series alloys with low-to-medium Mg but low Si concentrations seem to represent a transition case between the Al-Mn 3xxx series alloys on the one side and the high-Mg 5xxx series alloys on the other side. Especially, the microchemistry evolution during homogenization of alloy AA 5454 with quite large Mn-contents is characterized by $\text{Al}_6(\text{Mn,Fe})$ constituents and $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ dispersoids, which resembles the pattern observed in 3xxx series alloys with or without Mg. However, there is no indication of an $\text{Al}_6(\text{Mn,Fe})$ to $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ phase transformation of the constituent particles, which has repeatedly been reported for 3xxx series alloy. On the other hand, the microchemistry evolution in AA 5xxx alloys with low-to-medium Mg differs from the behavior of AA 5xxx series alloys with high Mg contents, which will be described in the next section.

AA 5xxx Alloys with High Mg

The most important AA 5xxx series alloys with high Mg contents include AA 5182 and AA 5083, which both contain some 4%–5% Mg together with different additions of Mn. The major constituent particles formed during solidification of commercial DC-cast AA 5182 ingots are commonly identified to be $\text{Al}_3(\text{Fe,Mn})$, $\text{Al}_6(\text{Mn,Fe})$, and Mg_2Si .^[68–70] Li and Arnberg observed metastable $\text{Al}_m(\text{Fe,Mn})$ instead of stable $\text{Al}_3(\text{Fe,Mn})$ and $\text{Al}_6(\text{Fe,Mn})$ in an as-cast AA5182 alloy.^[71] During subsequent annealing at 520°C most of the $\text{Al}_m(\text{Fe,Mn})$ particles transformed into the $\text{Al}_3(\text{Fe,Mn})$ phase with a lamellar structure.^[80] The exact phase selection during solidification depends on the alloy composition, most notably the ratio between the main alloying elements (besides Mg) Fe, Si, and Mn. With an increasing Si:Fe ratio, the type of the iron-bearing particles changes from Al_3Fe to $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ phase in the alloy; increasing Mn-contents shift the ratio from $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ to $\text{Al}_6(\text{Fe,Mn})$.^[70,71] In alloys with high Mg-contents notable fraction of eutectic Al_8Mg_5 particles can also be found.^[76,77] In Cr-bearing AA 5xxx alloys like the well-known AA 5083, some of the Cr is bound in the constituent particles, e.g., in the α -phase under formation of $\alpha\text{-Al}(\text{Fe,Mn,Cr})\text{Si}$.^[76,81–83]

In industrial practice, it is important to dissolve any Al_8Mg_5 particles that may have formed upon solidification in order to avoid partial melting of the rolling slabs during homogenization. The eutectic Al_8Mg_5 phase has a melting temperature of around 445°C, which is commonly exceeded during industrial homogenization practices. According to the phase diagram, Al_8Mg_5 is only stable at very low temperatures below 200°C. Hence, Al_8Mg_5 particles will dissolve during heating by solid-state diffusion processes. Thus, upon homogenization practices with low heating rates, e.g., in pit furnaces, all Al_8Mg_5 will safely be dissolved before reaching the eutectic temperature. Homogenization practices involving high heating rates, e.g., in pusher furnaces, are more critical if the Al_8Mg_5

particles are not completely dissolved when reaching the critical temperature of around 445°C.^[70] Here, a break in heating may be introduced at a temperature just below the eutectic temperature, e.g., at 435°C, so as to reduce the danger of partial melting.

Si is largely tied up in Mg_2Si constituent phases, which, at high Mg-concentration, are stable up to quite high temperatures (Fig. 14).^[80] Accordingly, at variance to the AA 5xxx alloys with medium Mg contents, there is no solute Si available, such that the dispersoids are preferably Si-free $\text{Al}_6(\text{Mn,Fe})$ particles.^[68,84,85] However, it should be noted that in 5xxx alloys with high Si-concentrations $\alpha\text{-Al}(\text{Fe,Mn})\text{Si}$ phase dispersoids have been observed as well.^[70,85,86] Hollinshead^[68] showed that the dispersoid characteristics in AA 5182 can be affected by the homogenization treatment, which, in turn, affects recrystallization that follows hot rolling: A low temperature preheat produced a fine dispersion of low-aspect ratio particles, which retarded recrystallization, whereas soaking at a high temperature followed by slow cooling produced coarse, needlelike dispersoids, which allowed rapid recrystallization.

In Cr-bearing alloy AA 5083, most of the Fe in the Al_6Mn dispersoids is replaced by Cr (Fig. 17), forming a phase $\text{Al}_6(\text{Mn,Cr})$; occasionally $\epsilon\text{-Al}_{18}(\text{Cr,Mn})_2\text{Mg}_3$ dispersoids have been observed as well.^[72,83,87] Given that diffusion of Cr in Al is extremely slow, the Cr-content of the dispersoids will supposedly increase their stability and, in turn, improve material properties of alloy AA 5083 at elevated temperatures.^[65] Again, different homogenization practices may be utilized to affect the downstream materials behavior. For instance, it was shown that the flow stress scales with the amount of Mn in solid solution or, vice versa, the flow stress decreases with increasing amount of precipitation of dispersoids.^[83,88] For the downstream recrystallization behavior—both recrystallization of the hot strip and recrystallization of cold rolled sheet

Fig. 17 STEM-EDS analysis of dispersoids in alloy AA 5083 after two-stage homogenization annealing, showing the presence of Mn and Cr^[83]

at final gauge—again a dependency on volume and size of the dispersoids, i.e., on the Zener drag, could be established.^[72,83,89] In conclusion, the above findings underline the strong impact of microchemistry changes upon homogenization on the downstream materials properties and, in turn, the importance of controlling the homogenization practice on the final gauge properties of Al sheet products.

CONCLUSIONS

The material properties of semifinished products from Al-alloys are controlled by the material microstructure, especially by the material constitution in terms of alloying elements in solid solution and, in turn, volume, size, morphology, and species of second-phase particles. These constitutional characteristics, conveniently summarized as microchemistry, have a direct impact on materials properties. Moreover, microchemistry affects the microstructure evolution during processing of Al semifinished products, e.g., upon deformation and recrystallization, which likewise affects downstream materials properties. In the present article, we summarize the phase selection upon solidification and the changes in microchemistry during subsequent homogenization annealing during industrial rolling of non-heat-treatable Al sheet alloys.

Because of the low solubility of the main alloying elements Mn, Si, and, most notably, Fe in Al, commercial Al-alloys will always comprise large eutectic phases. The composition of these so-called constituent particles will depend on alloy composition and, to a lesser degree, on solidification conditions. The most important constituent phases addressed in this article include Al_3Fe , $\alpha\text{-AlFeSi}$, $\text{Al}_6(\text{Mn,Fe})$, $\alpha\text{-Al(Fe,Mn)Si}$, and Mg_2Si . CALPHAD simulations, either for thermodynamical equilibrium or for rapid solidification (Scheil), facilitate identification of the constituent phases.

Upon subsequent homogenization annealing, the constituents may spheroidize and, depending on soaking temperature, can slightly grow or shrink. In some alloys, constitutional changes of the constituent phases occur, one of the most prominent examples is the $\text{Al}_6(\text{Mn,Fe}) \rightarrow \alpha\text{-Al(Fe,Mn)Si}$ phase transformation in Si-containing 3xxx series alloys.

After industrial DC casting, the Al matrix is usually heavily supersaturated with alloying elements. Thus, upon heating to homogenization temperature the supersaturated alloying elements start to precipitate in the form of finely dispersed particles. Many of these freshly formed precipitates re-dissolve at higher temperatures and, hence, are of little industrial relevance. However, they may serve as nucleation sites for other precipitates. Particles comprised of the well-known dispersoid-forming elements Mn, Fe, and Cr, especially $\text{Al}_6(\text{Mn,Fe})$ and $\alpha\text{-Al(Fe,Mn)Si}$, are stable to higher temperatures and hence survive

the homogenization treatment, although a fraction of them may be dissolved at high soaking temperatures.

The sequence of precipitation and re-dissolution of dispersoids allows controlling of the dispersoid state and the related downstream materials properties. For economic reasons, homogenization cycles should be as short as possible, which usually involves high soaking temperatures, with a reasonable safety limit to the alloy's solidus temperature. Lower homogenization temperatures are used when a high density of dispersoids is required, e.g., to produce a coarse-grained microstructure in brazing sheet. Two-stage homogenization practices comprised of a high-temperature soaking followed by a second step at a lower temperature lead to a significant coarsening of the dispersoids, which may facilitate recrystallization and, in turn, improve materials properties.

Open-Cell Foam Metal Production and Characterization by Aluminum Solid Mold Investment Casting

Kerem Altug Guler

Metallurgical and Material Engineering, Yildiz Technical University, Istanbul, Turkey

Abstract

Foam metals can be categorized in two basic classes: open-cell and closed-cell structures, which both have different numerous unique properties. Up to the present, several production processes have been developed for each class. Investment casting is known as a replication process for open-cell foam metal fabrication. Solid mold, which can be evaluated as a subtechnique of the investment casting, is specialized especially for small complex shapes with ultrathin sections. This work is a presentation of aluminum open-cell foam production with solid mold investment casting using two different kinds of patterns. The first one is “burnable,” in which liquid metal directly fills the shape of pattern and the second is “leachable,” in which metal takes the form of intergranular network shape of porous salt preforms.

Keywords: Aluminum; Foam metal; Investment casting; Open-cell; Solid mold.

INTRODUCTION

Investment casting has been used by ancient civilizations for jewelry, weapon, and art castings. In the modern world, its applications still include jewelry and art castings also turbine blades and numerous industrial components.^[1] Lost wax casting techniques are used for the production of components having complex shapes with thin walls. Solid mold technique is mainly applied for jewelry and dental castings with precious metals.^[2]

In terms of open-cell foam metal production, investment casting methods are placed in replication processes. Classic replication process can be defined as a general three-step procedure for the production of open-cell foam metals: (i) preparation of removable pattern, (ii) liquid metal infiltration, and (iii) pattern removal.^[3] In case of using burnable polymeric patterns, steps (ii) and (iii) must be replaced.

Polymeric foams can be used as a pattern for producing foam metal structure by conventional investment casting. Such polymeric open-cell foam (generally polyurethane) is infiltrated with a ceramic investment compound that after removal of the polymer by pyrolysis is then used as a mold. Evaporation of polymer template leaves behind negative image of the foam. After completion of infiltration and solidification, the mold must be decomposed to get foam metal structure.^[4,5]

Using of leachable preform is another way of foam metal production with replication process. In open-cell aluminum foam fabrication, sodium chloride (NaCl) is the well-known space holder preform material for years. The

process can be summarized in three simple steps of classic replication: (i) preparation of salt preform, (ii) infiltration and solidification of liquid aluminum alloy into preform, and (iii) dissolving of preform by water.^[6,7]

Open-cell foam metals have large accessible surface area and high-cell wall conduction giving remarkable heat transfer ability so they can be used as heat exchangers. Also, open-cell foam metals with controlled pore size can be used to filter high-temperature gases and fluids.^[5] A comprehensive applications list of the open-cell aluminum foam metals is given in Table 1.

In this article, production details and characteristics of open-cell aluminum foam metals, which were fabricated with solid mold investment casting technique, are presented.

PRODUCTION PROCEDURES

There are two kinds of patterns used for open-cell aluminum foam metal production with solid mold investment casting technique.

1. Burnable pattern.
2. Leachable pattern.

Production with Burnable Pattern

Polyurethane or rubber based polymeric foams (sponges) are burnable patterns, and they are removed to form mold cavity during the burnout (firing) sequence of

investment casting mold. The process starts with pattern preparation; natural rubber foam (Basaran Kaucuk,) in desired shape with cell structure 10 pores per inch (ppi) is attached to a wax (Freeman Aqua Green) sprue or runner by using wax soldering pen. The prepared pattern is placed to a rubber sprue base, which holds and fixes the flask around the pattern during mold making stage. A rubber foam pattern sample attached to the wax sprue is shown in Fig. 1.

The perforated stainless steel flask in appropriate dimensions with rubber base is placed around the pattern. The flask holds ceramic-based solid mold and perforated (having holes) flasks especially used in vacuum-assisted castings to provide high permeable zones on the mold. During mold making, these holes are covered with an

**Fig. 1** Burnable rubber foam pattern with wax sprue

adhesive band to keep ceramic slurry inside, and after slurry setting, adhesive band is removed.

In solid mold investment casting technique, mold making is carried out in one single step: filling the flask with prepared ceramic mold slurry. Gypsum-bonded investment powders are very suitable mold materials for aluminum alloys castings. These kinds of investment powders are designed and commonly used for gold and silver jewelry castings. Additionally, they can be useful for the most other nonferrous alloys. They are commercial products and contain plaster as binder and silica (quartz and cristobalite) as aggregates.

Castable ceramic slurry is obtained by mixing the investment powder (SRS, Eurovest) with water in producer-recommended ratios. Specially designed mechanical stirrer can be used for this process; during mixing and after filling the flask, vacuum is applied to remove air bubbles from the slurry. In special, working with burnable foam patterns, slurry vacuuming in the flask is extremely necessary and important operation for completely filling cell structure inside the foam pattern with ceramic slurry and removing the entrapped air. A schematic illustration of this process is shown in Fig. 2.

The gypsum-bonded slurry-filled flask is placed into a vacuum chamber and 10^{-5} Pa pressure is applied for 90 s. Excessive vacuuming may cause water evaporation and changes water/powder ratio. The slurry sets approximately in 15 min and mold leaves at least 1 h in undisturbed conditions. Before placing the mold to firing kiln, rubber base and adhesive bands are removed. First, dewaxing is carried out at 110°C then gypsum-bonded mold gradually fired up to 700°C – 730°C . In this stage, polymeric foam pattern pyrolysis and its residue ashes completely leave the mold. The graphic in Fig. 3 shows firing regime of the solid mold. Firing regime is designed according to volumetric changes of mold constituents accompanying to polymorphic transformations. Mold temperature is stabilized for appropriate casting temperature, and then molds are taken from the furnace and placed in vacuum-assisted casting machine. Vacuum pressure of 10^{-5} Pa is applied, and melting aluminum alloy is filled gravitationally to the mold from pouring basin. Schematic section of vacuum-assisted casting is given in Fig. 4.

**Fig. 2** Schematic illustration of slurry vacuuming in the flask

Fig. 3 Burnout regime of gypsum-bonded solid investment casting mold

Fig. 4 Schematic section of vacuum-assisted solid mold foam metal casting with burnable pattern

Vacuum application continues until the end of solidification, then mold is dipped into water for decomposition and cast part is taken out. Fired plaster easily dissolves in cold water; thus, mold removal occurs in seconds. Mold residues are carefully cleaned from foam metal by water blasting and brushing. A detached foam sample from the sprue is seen in Fig. 5.

In this casting technique, not only using of high-fluidity aluminum casting alloys is necessary, vacuum assistance

Fig. 5 Open-cell aluminum foam metal cast by solid mold investment casting using with burnable pattern

and high temperature of the mold also provides filling ability to wrought alloys. Almost all aluminum alloys can be cast in foam shape. In foundry works, A319 casting and A6063 wrought alloys were successfully cast at temperatures 735°C and 830°C, respectively.^[10]

Production with Leachable Pattern

Leachable patterns can be defined as preforms and differ from burnable ones by still existing in the mold during burnout and casting sequences; they are removed after casting. Pattern (or preform) material must resist firing and casting temperatures without melting, evaporation, or decomposition. The mission of the pattern in this process is being a space holder, and for aluminum foam production, the most suitable leachable pattern material is pure sodium chloride (NaCl) salt with 801°C melting point. It is an abundant low-cost material, and it can perfectly work with gypsum-bonded investment solid molds and aluminum alloys; best of all, it can easily be removed by only water leaching.

Supplying coarse salt granules (non-iodized brine salt) is a good starting point to refine them in desired grain size by mechanical grinding. Simple ball mills can be used for this purpose. Salt particle size is proportionally related to pore size of final foam metal structure. Of course, some factors like capacity of vacuum casting system and fluidity of aluminum alloy limit the fineness of using grinded particles. Salt particles are sieved and filled into cylindrical steel die, and unidirectional pressure is applied to form a compacted preform. Intergranular network of this preform forms foam shape of the cast part. It is apparent that final foam density is inversely proportional to compaction pressure and also the same process factors limit the maximum pressure level. Produced salt compacts are dipped into liquid paraffin to create thin protection wax layer. This is necessary for avoiding dissolution of salt by mold slurry, and it also makes easy attaching the preform to wax sprue. One prepared pattern sample is shown in Fig. 6.

Mold making and firing sequences are similar with previous burnable pattern technique. Casting process schema of aluminum foam metal production with leachable salt pattern is given in Fig. 7. After casting and mold knockout, space holder salt particles are removed in water by using a magnetic stirrer or ultrasonic cleaner. A cast foam sample is shown in Fig. 8. Foam castings of A380 alloy were carried out in experimental works with 730°C casting temperature.

RESULTS AND DISCUSSION

According to chemical compositions of A319 and A6063 alloys, which are given in Table 2, in the family of aluminum alloys, they are quite far away from each other. With relatively high Si content, A319 is a typical casting alloy and generally shaped with sand or permanent mold

Fig. 6 Leachable salt pattern with wax sprue

Fig. 7 Schematic section of vacuum-assisted solid mold foam metal casting with leachable pattern

techniques. Contrarily, A6063 is a well-known wrought alloy, and the extrusion process is the most preferred forming technique for it. In this present work, both of them were used to produce open-cell foam metals with a casting route by using burnable patterns.

Stereomicroscope images of the cast foams are presented in Fig. 9. It is seen that cellular structure of the foam was formed by each alloy. Depending on the 10 ppi cell

Fig. 8 Open-cell aluminum foam metal cast by solid mold investment casting using with leachable pattern

structure of the rubber pattern, average cell width of cast foams is approximately 2.5 mm. Furthermore, densities and average cell thicknesses are given in Table 3.

Density of the A319 foam is a little lower than A6063 foam; on the other hand, cell wall thickness is significantly higher. This situation directly depends on fluidity differences of the alloys. A319 fills and feeds sections of the cell walls much better and replicates the cell structure of the rubber foam more accurately. However, casting temperature of the A6063 alloy was increased up to 830°C, its fluidity level and feeding capacity did not reach to that of A319 alloy which was cast at 735°C.

Hintz et al. report a similar solid mold investment casting route for aluminum and copper open-cell foam productions by using polyurethane patterns with 10, 15, 20, and 30 ppi cell structures.^[8] Moreover, Mukai et al. represent AZ91 Mg alloy open-cell foam production with the same technique.^[11]

In casting work with leachable salt patterns, A380 alloy was used and its chemical composition is shown in Table 4. This alloy is most widely used in die-cast operations to fabricate integrated parts with thin sections. So it is known with high fluidity and relatively low solidification range.

In Fig. 10, stereomicroscope images of open-cell foam metal cast with A380 alloy are presented. Also, its characteristic properties are given in Table 5.

With a combination of hot (slow cooling) mold, vacuum assistance, and high fluidity alloy, extremely light and porous open-cell aluminum foam metals were produced and remarkable results were obtained. However, similar foam production with any wrought aluminum alloy with this kind of compressed salt pattern is almost impossible.

Table 2 Chemical compositions of A319 and A6063 aluminum alloys (wt.%)

	Fe	Si	Cu	Mn	Mg	Zn	Ni	Ti	Pb	Sn	Cr	Al
A319	0.7	4.0–6.0	2.0–4.0	0.2–0.6	0.15	0.2	0.3	0.2	0.1	0.05	—	Bal.
A6063	0.3	0.3–0.7	0.1	0.2	0.4–0.9	0.1	—	0.1	—	—	0.05	Bal.

Table 3 The characteristics of the open-cell aluminum foam metals cast with burnable patterns

Alloy	Density (g/cm ³)	Average cell wall thickness (mm)
A319	0.909	0.713
A6063	0.948	0.407

Table 4 Chemical composition of A380 aluminum alloy (wt.%)

Si	Fe	Cu	Mn	Mg	Zn	Al
8.62	0.824	3.091	0.2248	0.2804	0.9	Bal.

Table 5 The characteristics of the open-cell A380 alloy foam metal cast with leachable pattern

Density (g/cm ³)	Average cell wall thickness (mm)	Average cell width (mm)
0.360	0.282	0.897

this increasing is limited by the risk of preform melting, sodium chloride starts to melt at 801°C. In this situation, high melting point carbonate-type leachable space holder particles can be used instead of salt. Also, higher vacuum degrees or over pressure filling may be needed during casting.

Fig. 10 Stereomicroscope image of open-cell A380 alloy foam metal cast with leachable pattern

Because of low fluidity in molten state, wrought alloys may not fill the ultrathin sections of intergranular structure. To increase fluidity, casting temperature can be increased but

CONCLUSION

Casting operations are prominent production routes for open-cell foam metals. Solid mold investment casting, which is the most effective technique to fill ultrathin sections of intricate components, has a great potential for open-cell foam metal fabrication. Successful productions were carried out in experimental works; these unsurprising results are based on the nature of investment casting. Preheating of the mold to high temperatures prevents quick solidification of aluminum alloys; additionally applied vacuum sucks the liquid metal into narrow gaps and sections.

Actually, there is no any difference between conventional solid mold investment casting and open-cell foam metal production with burnable polymeric foam patterns. Polymeric foam templates are removed by the effect of heating and leave behind the empty negative foam structure that is filled by liquid metal. Unlike burnable patterns, leachable salt patterns still exist in the mold during casting, and they are removed from cast foam by water. The successful independent application with two different kinds of

patterns is another confirmation of the suitability of solid mold investment casting process to produce open-cell aluminum foams.

Optical Microstructures of Aluminum Alloys

S.V.S. Narayana Murty, Sushant K. Manwatkar, and P. Ramesh Narayanan

Material Characterization Division, Materials and Metallurgy Group, Vikram Sarabhai Space Center, Thumba P.O. Trivandrum, Kerala, 695 022, India

Optical microscopic examination is the primary method of examining the microstructures of aluminum alloys. They are performed in both as-polished and etched conditions. Aluminum alloys present some of the most complex microstructural features in terms of the nature of phases, constituent particles, and precipitates among various alloy systems. The microstructural changes that occur from the as-cast stage (namely, sand casting, die casting, or direct chill casting) through homogenization (a function of temperature and time) and thermomechanical processing to different temper conditions are wide and significant. No other alloy system has as many temper conditions as aluminum alloys. With the advent of tailor-made temper conditions to obtain balanced strength–toughness–corrosion resistance for advanced aerospace alloys, it is physical metallurgist's paradise to design and develop the cocktails of alloys with varying properties for specific applications.

Microstructural features of as-cast ingots include solidification mode, primary and secondary dendrite arm spacing, level of dendritic coring, presence of cast defects such as cavities/blow holes, gas/shrinkage porosity, interdendritic porosity, aligned/chain porosity, and abnormal grains or cracks. Usually, specimens from the top and bottom of the as-cast ingots are selected for macroscopic examination to assess the quality of the ingots. Microstructural details such as dendrite arm spacing are obtained from the center and periphery of the ingots to arrive at the homogenization time. These microstructural parameters are a function of the ingot diameter, processing conditions, and they help in the optimization of homogenization temperature and time for an existing alloy composition and help to arrive for the newly developed compositions. This is usually carried out in combination with the data obtained from differential scanning calorimetry, which gives information about the nature of phases present in the ingots.

Homogenization of as-cast ingots is carried out to reduce the macrosegregation, and it is an inherent feature in aluminum alloy processing. Microstructural examination of homogenized aluminum alloys as a function of time at a given temperature reveals the effect of homogenization wherein the signatures of dendritic coring are gradually eliminated to result in a fairly chemically uniform microstructure.

As-cast and homogenized ingots are subjected to thermomechanical processing through a series of operations such as extrusion, rolling, forging, or ring rolling. All these

operations are carried out at elevated temperatures. The microstructural changes that evolve during thermomechanical processing include breaking of the remnant cast structure to evolve wrought microstructure characterized by clear grains surrounded by high-angle grain boundaries, evolution of sub-grains, and orientation of grains and constituent particles in the direction of thermomechanical processing.

These thermomechanically processed materials (which also include cold rolled sheets) are subjected to varieties of temper conditions based on application requirements. The microstructural changes that occur in this step are predominantly submicroscopic that can only be viewed under a transmission electron microscope, as the process essentially involves low-temperature treatment.

Yet another interesting aspect of microstructural evolution in aluminum alloys occurs during their joining. Varieties of techniques are used for joining aluminum alloys including tungsten inert gas, metal inert gas, variable polarity plasma arc, laser, electron beam, resistance, friction welding, and friction stir welding. The microstructural features associated with these joining methods include weld bead solidification pattern, weld defects such as porosities, weld cracks, microstructures of weld/nugget, fusion zone, partially melted zone, and heat-affected zone. Welding of sheet to plate, sheet to forging, effect of plate/sheet orientation, or dissimilar welds present interesting microstructures.

Large numbers of aluminum alloys, both cast and wrought, are available in numerous temper conditions and are used extensively for various applications. In view of their high specific strength (strength-to-density ratio), they are used in critical aerospace applications. Great caution must be exercised in using high-strength aluminum alloys for critical applications as many of them are in their peak-aged tempers (T6) to derive the benefit of higher strength. These temper conditions have low immunity to stress corrosion cracking and are many times used in overaged tempers (T7) to alleviate the problem.

Microstructure is the fingerprint left over on materials due to processing, and their study is helpful to arrive at conclusions related to the reasons behind material failures. A failure analyst greatly depends on the microstructural examination of failed parts.

In order to successfully use aluminum alloys for a given application, they must be of right composition (including

those of minor alloying additions and permissible impurities) with right temper having the desired microstructure. Cradle to grave solutions must be provided with respect to the protection against environment from the ingot stage through manufacturing to the fabrication and final usage for high-strength aluminum alloys used in critical aerospace applications.

Microstructural quality control is exercised at different stages of aluminum alloy processing/manufacture with respect to both cast and wrought alloys. It is believed that this atlas will help the readers to understand the microstructural evolution as a function of their processing.

Plasma Electrolytic Oxidation (PEO) Coatings on Aluminum Alloys: Kinetics and Formation Mechanism

Alex Lugovskoy

Chemical Engineering, Ariel University, Ariel, Israel

Lyubov Snizhko

Fuel Technology, Ukrainian State University of Chemical Technology, Dnepropetrovsk, Ukraine

Abstract

In this review, the main kinetics and mechanism regularities of plasma electrolytic oxidation (PEO) of aluminum alloys are discussed. The material and heat balances of the PEO process, including anomalous gas evolution and possible thermochemical reactions are presented for the first time. Side effects accompanying spark discharges from both the surface and the electrolyte sides are analyzed. The influences of electrical regime (direct, alternative, and pulse current) on the rate of coatings growth are summarized from the electrochemical point of view. Different modes of anodic polarization and electrolyte composition (alkaline solutions with inorganic polymers and dispersed constituents) are discussed in the applicative aspect.

Keywords: Alkaline electrolytes; Aluminum alloys; Oxide-ceramic coatings; Plasma electrolytic oxidation; Soluble inorganic polymers; Spark discharges.

INTRODUCTION

Plasma electrolytic oxidation (PEO) is a technique for the production of hard oxide-ceramic coatings on lightweight metals such as aluminum, titanium, or magnesium. This process occurs in liquid alkaline electrolytes at voltages sufficient for the breakdown of barrier oxide layers formed at the metal surfaces. Sparks, arising as a result of the dielectric breakdown of a growing oxide film when the applied voltage exceeds a threshold value, are a characteristic peculiarity of the PEO. Short-living discharges move randomly on the treated surface and are accompanied by visible light emission and a specific noise. The sparks produce high local temperatures that melt the growing oxide layer resulting in amorphous or partly crystalline oxide-ceramic coatings. Another peculiarity of the process is a huge amount of steam and anodic gases released during the sparking period. The energy released in localized discharges causes a series of plasma-chemical processes such as gas evolution and refractory materials formation.

The PEO treatment of metals and alloys possesses some very attractive features as compared to the closely related to it anodizing. First, it allows the production of oxide layers on surfaces having complicated configuration. It is suitable for the batch “rack” processing of multiple specimens. Electrolytes, in which the PEO is performed, usually contain only simple, cheap, and environmentally friendly components. PEO allows the obtaining of hard (up to 24

GPa) coatings having low friction coefficients; the high surface porosity of the oxide layers is suitable to sealing and filling by polymers and lubricants. The PEO treatment is attractive for the production of anticorrosion, dielectric, heat-resistant, and even decorative coatings. As any other technique, PEO has several essential drawbacks: it requires higher voltages than other methods, the attachment of the current lead to a specimen may be problematic, damaged coatings cannot be stripped of a specimen by simple chemical dissolution, and the oxide layers are porous and may sometimes leach in aqueous media; they need to be stabilized and sealed. Still, PEO remains an important process from both the scientific and practical points of view.

The present article is aimed at the analysis of the existing data concerning the kinetics and the intimate mechanism of the oxidation processes on aluminum occurring under the influence of spark discharges. The influence of a polarization mode and the nature of an electrolyte on a dielectric breakdown development, the structure, and the principal properties of the oxide layer are discussed.

DEVELOPMENT OF THE BREAKDOWN

PEO, also referred to as anodic spark deposition or micro arc oxidation, is a high-temperature process based on anodizing accompanied by discharge events on the surface. Already in some early publications, it was supposed

that the breakdown of oxide layers is caused by the avalanche multiplication of electrons in the course of anodic ionization of an oxide.^[1-5] Particular attention has been paid to the sites at which breakdown initiates^[6,7] and the structure and morphology of the films after breakdown.^[8] Some data indicate that the breakdown may have a thermal nature and may be triggered by local heating caused by localized heat flows propagating during anodizing. The latter assumption may also include the possibility of initial electron avalanching. The rate-controlling steps of the film formation are determined by the ionic transport either at the metal/oxide or oxide/electrolyte interfaces, or within the bulk oxide. Current densities at microdischarges have been estimated as 50 kA m^{-2} , with a contribution of about 10 nm of coating material per event. The oxide layers are comprised of an amorphous and several crystalline phases, such as $\gamma\text{-Al}_2\text{O}_3$, $\alpha\text{-Al}_2\text{O}_3$ and mullite.^[9] The friable layer always exists on the top of the inner harder oxide coating.^[10]

Breakdown phenomena during the formation of barrier anodic films are most successfully interpreted by the model of an avalanche mechanism.^[11,12] According to this model, the breakdowns are a result of electron injection from the electrolyte/oxide interface and their multiplication in the film. This fact is supported by the established strong dependence of the breakdown voltage value on the nature and concentration of the contact electrolyte. Breakdown phenomena can be observed both in galvanostatic and potentiostatic modes of anodic polarization. However, breakdowns are typically recorded in galvanostatic–isothermal regimes, with the charge density increasing until the “first spark voltage” is reached and the first oscillation in the instant voltage is registered. As the

breakdown voltage value is reached, regular oscillations in the formation voltage continue to occur.^[13] Visually, as the breakdown voltage is reached, small sparks appear, their number rapidly increases and soon they cover the whole area of a specimen. The surface oxide layer is broken by the electric discharge at some point, and the electron avalanche causes the destruction and evaporation of the oxide film at that point. The crater on the surface is obliterated by the rapid formation of a new anodic layer, which is thicker than the surrounding oxide. Many authors^[14-17] have reported on the PEO process of aluminum, but the generation mechanism of microdischarges during the PEO process of aluminum is still not clearly understood. The possibility of breakdown emergence is determined by the kinetic characteristics of the oxide growth and requires a more detailed discussion.

PEO is a complex process combining concurrent events of oxide film formation, oxide dissolution, and dielectric breakdowns. Any of these events may dominate the overall process and the probability of such domination depends on the composition of both the metal and the electrolyte, as well as on the current regime employed. The ultimate stage of the PEO treatment is a quasi-steady state of persistent anodic microdischarges, during which the thickness, composition, and other parameters of the surface layer continuously change. The development of breakdown events in time is described in many papers^[14,15,18,19] and is shown in Fig. 1.

At high discharge temperatures and pressures (reaching about $2 \cdot 10^3^\circ\text{C}$ to $3 \cdot 10^3^\circ\text{C}$ and $\sim 10^2 \text{ MPa}$, respectively), solid products of electrolysis and adsorbed gel layers are deposited on the metal surface in the form of high-temperature oxide phases or glassy ceramic coatings.^[13] Depending on

Fig. 1 Development of breakdown events in time from slice 1 to 4

the purpose, the PEO treatment typically lasts between 5 and 180 min at current densities of 500–2000 A/m² and voltages of up to 1000 V. The electrolysis is always accompanied by intensive gas evolution, as is seen in Fig. 1, around the sparking metal specimens, and localized metal evaporation due to the plasma thermochemical reactions in the microdischarges. Careful determination of the material balance at the metal electrode requires the evaluation of the efficiency of the PEO process. So, the evolution rate and composition of anodic gaseous products, rates of aluminum chemical, and anodic dissolution in the electrolyte and oxide coating growth rate are the factors that determine the kinetics and mechanism of PEO process.

Some typical kinetic curves^[13,20] obtained in galvanostatic PEO are presented in Fig. 2. The process voltage may serve as a kinetic parameter, because in galvanostatic mode the only factor influencing the voltage is the resistance between the two electrodes, which depends practically only on the thickness of the oxide layer (assuming that the temperature and the electrolyte composition are approximately constant).

As can be seen in Fig. 2, the dependencies may be divided into four characteristic segments evidencing changes in the mechanisms of the anodic process. The initial rising segment is clearly visible on the curve for 0.5 and 1 g/L KOH, exhibits the maximum gradient on the voltage curve, and corresponds to the process of the conventional aluminum anodizing. In the next region, which is particularly pronounced for curve of 1.5 g/L KOH, the voltage rises more slowly, indicating a decrease in the oxide film growth rate; first, gas bubbles appear on the sample surface in this region. In the next region, the process is distinctly different: for curves of 1 and 1.5 g/L KOH, the voltage still increases (though even more slowly); this usually corresponds to oxide recrystallisation and macroscopic defect formation in the film structure; however, for the curves of 2 g/L KOH the oxidation stops and dissolution of the metal starts. The plateaus in the curves begin with intensive gas evolution, which creates a background for the onset of plasma microdischarge phenomena at the sample

Fig. 2 The kinetics of PEO in the galvanostatic mode at 935 A/m² in an alkaline electrolyte containing different concentrations of KOH

surface. Such a behavior was reported in numerous papers for dependencies of current densities^[13] and electrolyte concentration.^[21,22]

As can be seen in Fig. 2, it is the initial stage of oxidation that determines the possibility of the formation of a barrier layer having sufficient dielectric properties for the subsequent breakdown. The characteristics of this layer are defined by the electric mode of electrode polarization^[12,13,23] and by both the alloy^[24–27] and electrolyte composition.^[6,28,29] Despite the fact that electrical regime has no significant influence on the initial stages of PEO, it seems to be the most varied factor of the process due to the large difference in power supplies used by different authors. At the same time, the type of polarization defines the rate of coating growth and mechanism of charge transfer.

THE MAIN ELECTRICAL MODES USED IN PEO

In dilute electrolytes, the oxidation can be carried out in galvanostatic, potentiostatic (current and potential, respectively, are kept constant during the entire process) or mixed regimes, for which the process starts at a fixed current and is then kept at a constant voltage. A detailed description of the oxidation kinetics is given in a comprehensive review.^[30] For the simple oxidation that is not accompanied by any chemical or thermochemical by-processes, the film thickness is proportional to the amount of the positive electricity Q in accordance with Faraday's law.

In the galvanostatic mode (steady-state regime), the anodization proceeds at a constant field intensity E :

$$E = \frac{\Delta U}{\delta}, \quad (1)$$

where ΔU is the difference between the final U_f and the initial U_0 voltages.

The relationship between the ion current i_i and E is expressed by the exponential dependence known as Gunterschultze—Betz equation:

$$i_i = i_0 \exp(\beta E), \quad (2)$$

where both i_0 and β are temperature-, and metal-dependent parameters. For aluminum oxide,

E , i_0 , and β are in the range of 10^4 – 10^5 V/m, $1 \cdot 10^{-15}$ – $3 \cdot 10^{-1}$ A/m², and $1 \cdot 10^{-9}$ – $5.1 \cdot 10^{-8}$ m/V, respectively.^[5]

For the conventional anodizing, not complicated by chemical or thermochemical processes, the dependence of the coating thickness δ on the charge density q is practically linear, and the coefficient of proportionality γ is comparable with the value calculated from Faraday's laws

$$\gamma = \frac{d\delta}{dq} = \frac{M(1-\alpha)}{\rho nF}, \quad (3)$$

where M is the molar mass of oxide, δ is the oxide thickness, ρ is the oxide density, $(1 - \alpha)$ is the current efficiency, n is the number of electrons in the reaction of metal ionization, and F is Faraday constant.

Obviously, as the current changes by an order of magnitude, the field intensity only changes by less than 10%.

Combining the Eqs. 2 and 3, the following expression for γ is obtained:

$$\gamma = \left(\frac{i_0 M}{\rho z F} \right) \exp \left(\frac{\beta \Delta U}{\delta} \right). \quad (4)$$

So, at the 100% efficiency the voltage–time response during the anodizing of aluminum can be calculated as follows:

$$\frac{dU}{dt} = \frac{E i M}{\rho n F}. \quad (5)$$

The electric field strength E for current densities 1–100 Am^{-2} can be calculated from the expression of Harkness and Young

$$i = i_0 \exp - [(W - qaE) / kT], \quad (6)$$

where $i_0 = 2.24 \cdot 10^{-11} \text{ A m}^{-2}$, $W = 1.3 \text{ eV}$ (potential barrier), $q = 3$, $M = 0.102 \text{ kg mol}^{-1}$, $\rho = 3100 \text{ kg m}^{-3}$ (the density of anodic alumina), $a = 0.295 \text{ nm}$, k is Boltzmann's constant, and T is the temperature.^[31]

If the film grows at less than 100% efficiency due to the field-assisted ejection of Al^{3+} ions to the electrolyte, the slope predicted from Eq. 5 is reduced in proportion to the fraction of the ionic current associated with the ejection of Al^{3+} ions. Therefore, the efficiency of film growth can be calculated from the ratio of slope determined from an experimental voltage–time response to that calculated from Eq. 5 for anodizing at 100% efficiency. The electric field intensity is dependent on the total ionic current, including both the ionic current associated with the film growth and that associated with the field-assisted ejection of Al^{3+} ions to the electrolyte, and hence, it is independent of the efficiency of film growth.

In the potentiostatic mode (nonsteady-state regime), the current increases sharply from the beginning of anodizing, but then, as the film growth, the current falls. The logarithmic anodic current density decreases linearly with the logarithmic anodizing time at the initial stage. The slope of the “ $\ln i_a$ vs. $\ln t$ ” plot at the initial stage shows higher values with the increase of the applied anodic potential. So, the rate of the growth of the barrier type anodic oxide film on metals follows a linear relationship

$$i = A t^{-n}, \quad (7)$$

where A and n are empirical constants.

During the film growth, the field intensity decreases. For this case:

$$\ln i = \ln i_0 + \frac{B(U_0 - U_f)}{\delta}. \quad (8)$$

At the potential U_1 at the time t_1 , the oxide thickness δ_1 can be calculated as follows:

$$\frac{B(U_1 - U_f)}{\delta_1} = K \ln t_1, \quad (9)$$

where $K = d \ln i / d \ln t$, B and i_0 are Gunterschultz constants that have been found by galvanostatic and potentiostatic modes and are approximately the same: $(1.1\text{--}1.4) \cdot 10^{-8} \text{ m/V}$ and about 10^{-4} A/m^2 , respectively.^[32]

The current decay is described by the following equation:

$$\frac{1}{i - i_1} - \frac{1}{i_0 - i_1} = B(t - t_0), \quad (10)$$

where $B = \frac{1}{v} \ln 2 \cdot \frac{C}{1+q} \cdot \frac{t_f}{\tau t_i}$, i and i_1 are the total current and the leakage current respectively, t_0 and t are the initial and end times of holding the voltage constant, v is the drift velocity, C is the constant of integration, q is the ratio of the mobilities of electrons and ions, t_i is the time for getting ionization energy (I), τ is the mean time between ionization collisions, and t_f is the time for ionizing collisions. Constant B can be found experimentally. This theory can also be applied to the growth under constant current and the agreement between theory and experiment is quite good.^[3]

The use of various **nonsteady-state modes** has become very popular recently.^[33] Since neither the current nor the voltage is constant, two ways of representation may be used. The first is to express the signals as their maximal (peak) values and the other is the use of effective values, which are simply the root mean square (RMS). The RMS value of any function $y = f(t)$ over the range $t = a$ to $t = b$ can be defined as^[34] follows:

$$\text{RMS value} = \sqrt{\left(\frac{1}{b-a} \int_a^b y^2 dt \right)}. \quad (11)$$

For most cases, sine-shape voltages are used and then Eq. 11 can be simplified to $V_{RMS} = 0.7 V_m$ or $V_m = 1.4 V_{RMS}$, where V_{RMS} is the effective voltage and V_m is the maximal voltage. Similar equations also apply to the current. Other simplified equations can be developed for other shapes of waveforms. Normally, RMS values are given for all AC experiments, unless explicitly stated that peak values are used.

Most simple multimeters, voltmeters, or ammeters measure RMS value assuming a pure sinusoidal waveform. For

finding the RMS value of a non-sinusoidal waveform, an oscilloscope is required. The RMS value of a sinusoidal waveform gives the same heating effect as a DC current of the same value. That is, if a direct current passes through a resistance of R , the DC power consumed by the resistor as heat will therefore be I^2R . Then, if an alternating current flows through the same resistance, the AC power converted into heat will be $i_{RMS}^2 \cdot R$. So, for example, an alternating current of 10 A will have the same heating effect as a direct current of 10 A and a maximum value of 14.14 A.

A distinct difference between AC- and DC-anodizing is the generation of hydrogen gas on the specimen during the cathodic cycles; thus, at 50 Hz, the film growth is interrupted after periods of 0.01 s, as the gas evolution proceeds at suitable locations on the filmed alloy surface during the cathodic half cycle. Additionally, secondary reactions arising from anion reduction occur during AC anodizing.^[35] The charge efficiency, ϵ_Q , defined as the ratio of the amount of aluminum ions generated to the amount calculated from the charge passed, may be determined from the expression

$$\epsilon_Q = \frac{(W_1 - W_3)}{MQ_a / 3F}, \quad (12)$$

where W_1 and W_3 are the weights of the specimen before the anodizing (g/dm²) and after the removal of the anodic film (g/dm²), respectively, Q_a is the anodic charge density (C/dm²), M is the molar mass of aluminum (27 g/mol), and F is Faraday's constant (96500 C/mol).

The anodic oxide formation efficiency, ϵ_{of} , is a measure of the amount of oxidized aluminum that forms anodic oxide, and it is calculated from the following expression that takes the charge efficiency into account

$$\epsilon_{of} = \frac{100(W_2 - W_3)}{\epsilon_Q M_{ox} Q_a / 6F}, \quad (13)$$

where W_2 and W_3 are the weights of the specimen after anodizing (g/dm²) and after removal of the anodic film (g/dm²), respectively, $Q_a/6F$ represents the theoretical amount of oxide formed at 100% charge efficiency (mol), M_{ox} is the molar mass of alumina (102 g/mol), and $W_2 - W_3$ represents the weight of the anodic film.

Anodic charge density for a DC process Q_{DC} can be calculated as $Q_{DC} = it_{ox}$ and for an AC process as $Q_{AC} = (\sqrt{2}) \cdot i_{RMS} t_{ox} / \pi$.

For the conventional oxidation, it was shown^[34] that for an AC process about 10 ± 3% of the anodic charge is lost rather than consumed for aluminum oxidation. However, aluminum cations produced should form the oxide with the efficiency similar to that of DC anodizing (around 60 ± 3%). The anodic current is partly ionic (because areas damaged by a discharge are instantly self-healed) and partly capacitive (because the reestablishment of a high electric field is required for ionic migration across the

existed and repaired barrier layer oxide). During a negative half-period, hydrogen gas evolution causes local punctures and damages in the barrier oxide layer. During an anodic half-period, the charge density is $q_a = \sqrt{2} \cdot i_{RMS} / \pi f$, where f is the current frequency. A part of this charge q_{re} is consumed for the film recovery on time t_{re} including the reestablishment of the electric field for ionic migration: $q_{re} = (\sqrt{2} i_{RMS} / 2\pi f) [-\cos 2\pi f t_{re} + 1]$. The electronic resistance of alumina is extremely high (10^9 – 10^{12} Ωm), and the impedance amplitude of the oxide is reduced to $|Z_{ox}| \cong (2\pi f C_{ox})^{-1}$, where C_{ox} is the capacitance of the barrier layer $C_{ox} = \epsilon_0 \epsilon_r A / \delta$ [for $\delta = 20$ nm and $A = 1$ dm² the value $C_{ox} = 43$ μF ($\epsilon_r = 9.8$)]. At $f = 5$ Hz, $2\pi f C_{ox} = 1.3 \cdot 10^{-3}$ Ω⁻¹ which is still at least an order of magnitude higher than $R_{ox}^{-1} = 5 \cdot 10^{-4}$ – $5 \cdot 10^{-7}$ Ω⁻¹. Here, ϵ_0 is the permittivity of the vacuum (8.85×10^{-12} F m⁻¹), ϵ_r is the dielectric constant of aluminum oxide, A is the surface area of the capacitor (m²), δ is the thickness of the dielectric layer, ξ is the proportionality constant between the barrier layer thickness and the potential ($\xi = 1.3 \cdot 10^{-9}$ mV⁻¹) and U is the amplitude of the voltage across the barrier layer oxide (V). A simple expression for the capacitive current i_{cap} can be obtained: $i_{cap} = (2\pi f \epsilon_0 \epsilon_r) / \xi$. Therefore, the capacitive current density varies only with frequency, being independent on the imposed AC current density.^[35] The ratio of the capacitive current density, i_{cap} , to the direct anodic current density, i_a , corresponding to the charge in one anodic cycle, q_a (with $i_a = 2f q_a$), gives us the percentage of the anodic charge consumed for reestablishing the high field. Apparently, i_{cap} linearly depends on the frequency f . Particularly at increased frequency, less anodic charge is available for oxidation, so charge efficiency is reduced. At higher frequencies, an almost mesh-like porous film is formed which is more susceptible to chemical dissolution, proceeding due to the electrolyte penetration into the oxide film.

Oxygen gas evolution, which is another plausible source of anodic charge loss, is unlikely on oxide-covered aluminum, but quite possible on alloy fragments protruding at the metal/film interface.

During a cathodic half-period, hydrogen forms as a result of water reduction: $2H_2O + 2e \rightarrow H_2 + 2OH^-$. The greater the barrier layer thickness, the greater the cathodic potential for the hydrogen gas evolution. As is said above, at the AC polarization the main loss is caused by the capacitive buildup of the high electric field, necessary for ionic migration providing the oxide formation. The second loss is caused by the oxygen gas evolution. Higher frequencies of the AC processing reduce the charge and oxide formation efficiencies due to larger capacitive currents. Hydrogen gas evolution evolves during negative half-periods and causes the activation of flaw sites in the oxide barrier layer. Hydrogen gas increases the electrolyte resistance in the flaws and pores of the anodic film, thus introducing a large voltage drop across the layer.

Typical kinetics dependences of the initial stage of PEO are presented in Fig. 3.

Fig. 3 Typical kinetic dependences for the DC galvanostatic, AC galvanostatic (left), and DC potentiostatic (right) modes of PEO of aluminum alloys

Today, it is generally accepted that the oxides simultaneously grow at both interfaces, i.e., at the metal/oxide interface due to the transport of Al^{3+} and at the oxide/electrolyte interface due to the transport of the oxygen O^{2-} ion.^[25,36] The transport numbers of Al^{3+} ions, $t_{\text{Al}^{3+}}$, and oxygen, $t_{\text{O}^{2-}}$, at the current density 50 A/m were reported as 0.45 and 0.55, respectively.^[37] For a general case, the current density passing across the oxide film can be written as^[38] follows:

$$i = i_a + i_c + i_e, \quad (14)$$

where i_a , i_c , and i_e are the current densities contributed by O^{2-} , Al^{3+} ions, and electrons. For the conventional anodizing, the electronic conductivity in the aluminum oxide is negligibly low, so the ionic current ($i_i = i_a + i_c$) is the predominant mode of electric charge transportation. Under the sparking conditions, the ionic conductivity practically disappears and electrons become the main charge carriers.

THE INFLUENCE OF THE COMPOSITION OF ELECTROLYTES ON PEO KINETICS

Despite the thermodynamical instability of aluminum ions at the $\text{pH} > 12$, when the soluble aluminate $\text{Al}(\text{OH})_4^-$ is the preferred form, alkaline media retard the dissolution of oxide film on aluminum and accelerate its growth.^[20] The concentration of the aluminate ions at the oxide film/solution interface increases with the increase of the applied electric field directed toward the solution, thereby reducing the rate of the chemical film dissolution by the attack of hydroxyl-ions.^[21] In the general case, four characteristic areas can be seen in the U vs. t plots for the galvanostatic mode (*cf.* Fig. 2), evidencing changes in the mechanisms of the anodic process.^[13] At the beginning of the process, the maximum slope of the voltage–time curve, corresponding to a conventional aluminum anodizing, is observed. In the next region, a decrease in the oxide film growth rate

is observed and first gas bubbles appear on the sample surface. At some point, breakdowns occur on the electrode surface. The initial slope of voltage–time curves for the barrier oxide layer growth is proportional to the applied anodic current density, but the slope during the micro-discharging stage does not change with the applied anodic current density. The voltage is dependent on the anodic charge passed, but not on the applied current density. The sites of breakdown correspond to local variations in the oxide layer thickness and fluctuations in the concentration of the electrolyte on the interface and, therefore, depend on the injection of primary electrons. With the increase of the current density, the duration of the second region diminishes and becomes practically indistinguishable at high (>1000 A/m²) current densities. At the third stage, the slope of voltage vs. time rises again; this usually corresponds to the oxide recrystallization and defect appearance in the film structure. The last and longest stage of the process is evidenced by intensive gas evolution and plasma micro discharge phenomena on the surface. Discharges reach (or approach) a steady state, so that the only observable change is the gradual transition from numerous small and frequently appearing sparks to more rarely distributed larger flares having longer lifetimes. As the PEO processing time and the number of breakdowns increase, the surface of the formed oxide becomes rougher. The amplitude of the voltage oscillations increases, while their frequency remains unchanged. The voltage oscillations (i.e., essentially, the number of breakdowns) are also almost insensitive to the current density: a significant increase in the current density causes only a slight decrease in the amplitude of these oscillations. In fact, this means that the number of breakdowns and the degree of the surface modification of the oxide depend more on the charge density passed (Q_p), rather than on the current density. A tendency to reduce the sparks amplitude with increasing current densities (i) is observed,^[16] whereas the number of breakdowns remains constant. Such a result could be explained assuming that breakdowns at higher

current densities gouge wider craters, though this aspect of the process has not been studied deeply enough.

In the galvanostatic mode, the increase of potential depends on the concentration of an alkali (Fig. 2, *cf.* also Ref. [21]). In the solution of 0.5 g/L NaOH (Fig. 2), an initial, virtually linear increase of the voltage is followed by a sudden reduction in the slope of the voltage–time curve around 620 V at which microdischarges start to appear. In more concentrated solutions (1 and 1.5 g/L NaOH), the voltage increases rapidly in the initial stage for about 40 s, then it continues to increase more slowly and reaches a film breakdown voltage of about 500 V. It can be seen that during the generation of microdischarges on the aluminum surface, voltage increases very slowly with time. The breakdown voltage becomes lower as the concentration of NaOH increases. The plateau, for which the discharges are formed in a kind of a steady state and the voltage slowly increases with the growth of the thickness of an oxide layer, cannot be achieved at 2 g/L NaOH, due (probably) to the prevailing rapid dissolution of the oxide film caused by the increased chemical attack by OH[−] ions:

where Al_{ej}^{3+} are the cations, ejected through the oxide film.

One of the possible mechanism of the processes occurred at the film/solution interface is the vacation migration:^[21]

where $\text{Al}^{3+}(\text{aq})$ is the aluminum ion in the aqueous solution, $\text{O}_{\text{O}}(\text{ox})$ is the normal oxygen ion in the regular site of the oxide film, and $\text{H}^+(\text{aq})$ represents the hydrogen ion in the aqueous solution.

In alkaline solutions, new oxide sites should be formed at the oxide/electrolyte interface by adsorption and decomposition of OH[−] ions which decreases the pH near the oxide surface.

The decrease of breakdown voltage observed with increasing NaOH concentration is attributable to the increased concentration of OH[−] ions adsorbed on the oxide surface at high electric field. This causes chemical dissolution, thereby increasing the applied electric field across the oxide film. The rate of the insertion of OH[−] ions into the oxide film will be affected by the concentration of $\text{V}_{\text{O}}^{2+}(\text{ox})$ at the oxide surface and the applied electric field. As too

large amount of hydroxide ions adsorbed on the oxide surface, the oxide film would dissolve. As is seen in Fig. 2, in the electrolyte containing 2.0 g/L KOH, the voltage increases initially up to 150 V and then slowly decreases. This can be explained by the dissolution of the aluminum oxide after the formation to a certain steady-state thickness. It happens if the rate of chemical dissolution of the oxide film by OH[−] ions exceeds the rate of the oxide formation. A relatively uniform alumina film of high purity forms at high efficiency over a limited voltage range. For the film formation at relatively high voltages and at high current densities, which is characterized by the low overall efficiency, a nonuniform film develops with scalloped interfaces and with channels penetrating the cross section of the film.^[36]

The efficiency of the film growth in sodium hydroxide electrolyte of pH 11 at 50 A m^{−2} was assessed by comparing the initial slopes of the measured voltage–time curves with that for the film growth in ammonium pentaborate under similar conditions, for which the film formation occurs at an efficiency approaching 100%. At voltages exceeding ~200 V, a slight downward curvature was observed; the latter increased at higher voltages and resulted in about a 40% increase in the time to reach the breakdown voltages. This was partly caused by the breakdown, accompanied by gas evolution and sparking. The coatings formed consisted of Al₂O₃, presumably formed from the Al(OH)₃, arisen due to hydration of the surface layer or as a by-product of the dielectric breakdown. The metal–film interface showed a nonuniformly scalloped appearance with corresponding protuberances on the border oxide/electrolyte with no evidence of regular pores. The reduced efficiency of the oxide growth was associated with a nonuniform film growth, related to local heating and current concentration in conducting channels within the local spaces in the film.

As abovementioned, at the efficiency of film growth close to 100%, about 40% of the film material is formed at the film/electrolyte interface due to the outward migration of Al³⁺ ions. At less favorable conditions for the film growth, a portion of the Al³⁺ ions migrating to the film/electrolyte interface may be ejected to the electrolyte at a high electric field. Consequently, relatively less of the barrier film thickness is formed by the addition of alumina at the film/electrolyte interface during the advancement of the voltage to a preset value, while relatively more of the film is formed at the metal/film interface by the inward migration of O^{2−} ions. The reduced efficiency is usually associated with the film growth at relatively low current densities.

A highly efficient film growth can occur during anodizing at normally inappropriate values of current density, temperature, and pH if ejection of Al³⁺ ions to the electrolyte is suppressed by modification of the composition of the film/electrolyte interface, either from the film side or the electrolyte side. The presence of “inhibitor” anions in the electrolyte prevents the ejection of Al³⁺ ions from the

film. Formation of gels in some inorganic polymers including silicate and tungstate anions and their influence on the anodic film growth were studied by Morlidge et al.^[31]

The most popular electrolytes in PEO of aluminum are alkaline solutions of soluble silicate glass.^[39–41] They are commonly represented by the general formula $x\text{SiO}_2 \cdot \text{M}_2\text{O}$, where M is an alkali metal (i.e., Na) and x is the silicon to cation ratio (i.e., $\text{SiO}_2/\text{Na}_2\text{O}$) also referred to as the silicate index. In the presence of an electrolyte containing soluble inorganic anions, for example, silicate aluminum dissolution is controlled by the competitive adsorption of OH^- and SiO_3^{2-} ions on the oxide surface.^[21] The adsorbed SiO_3^{2-} ions will reduce the rate of chemical dissolution of the oxide film by reducing the concentration of hydroxyl ions adsorbed on the oxide surface, so that microdischarges can be generated at relatively high pH of the electrolyte. It was proposed^[42] that there are three different phases in the interaction between the anodic oxide film and the sodium silicate solution: the activation of the surface, the attack of the oxide film, and the initiation and growth of the silicate layer. From the beginning of the interaction, the aluminum oxide surface is etched. Due to the dissolution of the anodic layer, the oxide in contact with the solution becomes thinner, because the formation of aluminate ions $[\text{Al}(\text{OH})_4]^-$ and the evolution of hydrogen occur. During the second phase of the interaction, the process is dominated by the competition between the adsorption of the silicate on the alumina surface and the dissolution of the oxide film. After the adsorption, granular structures and/or particles are present on the surface and no oxide dissolution is observed.^[43] The areas of the oxide film covered by a sufficient amount of silicate are protected from dissolution. By contrast, the areas of the oxide insufficiently covered by the silicate deposition are attacked and the dissolution continues until the barrier layer is completely removed. At the ratio $\text{SiO}_2/\text{Na}_2\text{O} = 1$, the hydrolysis of soluble glass can be written by the following equation:^[44,45]

At highly alkaline pH, the particle $(\text{HO})_{4-x}\text{SiO}_x^{x-}$ from the monomeric silicate reacts with aluminate ions $[\text{Al}(\text{OH})_4]^-$:^[42]

One can see that in the alkaline silicate solution (pH ~ 13) both the aluminosilicate anions and the oxide surface are negatively charged. The presence of colloidal particles in the solution was confirmed showing that almost all the particles have a diameter between 1 and 32 nm.^[43] In these conditions, the deposition of silicate anions at a negatively charged oxide surface requires the presence of a potential coagulating agent, usually a small concentration of polyvalent metal ions. It was suggested^[43] that monovalent

ions (e.g., sodium) have a similar effect, if the concentration is high enough. Monovalent sodium cations upon hydration are surrounded by six water molecules. Therefore, the hydrated Na^+ ions are adsorbed at the negative sites of the alumina surface, forming a neutral complex. When an uncharged area of a particle comes to the oxide surface, the Na^+ ions coordinate with the oxygen atoms of silanol, forming a coordination linkage between the particles and the surface. In this way, a number of Na bridges are formed. After the formation of the first chemisorbed layer, further adsorption occurs due to the physical interaction with the chemisorbed layer already present on the alumina surface. After rinsing, a significant part of the adsorbed silicate is redissolved in water and only the silicate directly bound to the anodic oxide remains.

The development of gel layers during anodizing, and their influence on the efficiency of anodic films growth, has been examined for the formation of films at constant current density on aluminum in saturated potassium antimonate electrolyte and 0.1 M sodium molybdate, sodium silicate, and sodium tungstate electrolytes.^[21] The gels are produced immediately above the growing anodic films by the reaction of H^+ ions, generated at the film/gel interface, with the electrolyte anions to form uniform layers of hydrated oxide:

Gel obtained from silicate solutions at pH = 11 consists of Si ($3 \cdot 10^{19}$ at/m²) with the atomic ratio of Si/Al of $3 \cdot 10^{-3}$ in the film. The reduced gel thickness at low-current densities is probably due to the greater role of chemical dissolution of the gel layer at low rates of anodic film growth. The thicknesses of the gel layers increase at constant rates with thickening of the anodic films, although the efficiencies of the gel formation per se are relatively low. The thickest gels are obtained following anodizing in an antimonate electrolyte, possibly reflecting a more favorable rate of gel formation, relative to its rate of dissolution, than that for other gel layers. The gel layers promote the formation of anodic alumina at high efficiency by reducing or eliminating field-assisted ejection of Al^{3+} ions to the electrolyte, which would occur in their absence.

THE INFLUENCE OF ALUMINUM ALLOYS COMPOSITION ON PEO KINETICS

The movement of cations or anions through oxide films is explained in.^[46–48] Anodic films formed at 5 mA/cm² on Al–27 at.%Mg and Al–32 at.%Mg alloys in 0.1 M sodium hydroxide electrolyte at 293 K develop at relatively high efficiency. The films comprise two layers: the inner layer and the outer layer, respectively, relatively depleted and enriched in magnesium as compared with the alloy composition. The layered compositions of the anodic films are due

to migration of Mg^{2+} ions being faster than that of Al^{3+} ions in the inner, alumina-rich layer and to differences in ionic resistivity of the magnesium-depleted and magnesium-rich films. The thickness of the inner layer relative to that of the film decreases with the increase in magnesium content of the alloy. For an alloy composition of 40 at.%Mg, a change in the mechanism of film formation may occur, since the inner layer may no longer be sustained. Enrichment of alloying elements during anodizing can take place in Al–Mg alloys similar to that in high purity magnesium and aluminum, as was demonstrated by the enrichment of tungsten in an Al–26 at.%Mg–1 at.%W alloy.^[49]

As a contribution toward the understanding of the electrochemical behavior of magnesium containing second-phase particles in aluminum alloys, the formation of barrier-type anodic films on sputtering deposited Al–21at.%Mg was examined by analytical transmission electron microscopy.^[50] Amorphous anodic films of uniform thickness develop on the alloy in ammonium pentaborate electrolyte of pH 8.3 at current densities between 0.1 and 100 mA/cm². The films contain incorporated magnesium species that reduce the electric field required for the film growth. The magnesium species migrate through the film about three times faster than Al^{3+} ions and are lost to the electrolyte on reaching the surface of the film, leading to a reduced efficiency of growth of about 92%. Further, the growing films can detach from the alloy, particularly at relatively low current densities. In strongly alkaline conditions, the comparatively rapid transport of magnesium species and the stability of the resulting magnesium rich surface regions of the film permit a highly efficient film growth in sodium hydroxide solution at pH = 13.^[50] The voids in the film were suggested^[51] to arise due to the low Pilling–Bedworth ratio of MgO/Mg (0.81) as compared to that of $\text{Al}_2\text{O}_3/\text{Al}$ (1.65), with voids caused by the different volumes of an oxide formed following the oxidation of an alloying element and aluminum.

At the same time, the oxides grown by PEO are in-depth growing layers and therefore the alloy microstructure (mainly, the presence of intermetallics) may affect their morphology and properties.^[52] Copper is one of the main alloying elements in various aluminum alloys. For example, aerospace alloys have relatively high copper contents, typically about 4% mass, that can be distributed in segregates, dispersoids and second phase particles, and in the solid solution matrix regions, according to the particular thermomechanical processing route and heat treatment of the alloy. The reason for the enrichment is that the dissolution of an alloy proceeds through an amorphous, alumina-based film. Thus, the metal atoms are oxidized at the alloy/film interface and then migrate through the film before entering the solution. Copper atoms in a solid solution in the aluminum matrix cannot be oxidized initially, which is related to the higher equivalent Gibbs free energy for the formation of copper oxide relative to that for the formation of alumina, leading to an increased concentration

of copper in the alloy, in a layer of thickness up to 2 nm, during the early stages of treatment. Oxygen generation, a consequence of oxidation of copper in the alloy, has a strong dependence upon grain orientation, which suggests an alignment of clusters along certain crystallographic planes. Evidence from other aluminum alloys indicates that the levels of enrichment are not affected significantly by the rate of oxidation.^[53]

Anodic oxidation of Al–Cu alloys, containing about 1 at.%Cu, leads to enrichment of copper in a layer of alloy about 1–2 nm thick located just beneath the alumina film. The level of enrichment must rise to the range $5\text{--}6 \cdot 10^{15}$ Cu atoms/cm² for copper atoms to be oxidized. The level of enrichment of copper then remains approximately constant during the further film growth. At the same time when copper species enter the film, numerous bubbles of oxygen gas develop within the film, the gas being at high pressure. Oxygen is eventually released from the film when the bubbles rupture. The formation of the bubbles influences the uniformity of flow of ions through the film, with additional variations occurring due to the healing of ruptured film. The consequence is the roughening of the alloy/film and film/electrolyte interfaces.^[54]

Along with a counter motion of cations Al^{3+} and anions O^{2-} , copper species present in the film in low concentration are also mobile. Enrichment of copper preceded anodizing, and hence, incorporation of copper species into the anodic film was practically immediate.^[54] For the bubble-free film, the relative amounts of copper in the film and in the alloy indicate an average migration rate of the copper species ~ 2.4 times faster than that of Al^{3+} ions. The copper species reaching the surface are lost to the electrolyte, possibly through ejection by the electric field; hence, there is no copper-rich surface layer. The copper species are distributed less uniformly in the bubble-containing film, with some concentration of copper in the middle regions, where the number of bubbles is highest. Cracking and healing of the film, when bubbles burst, may also affect the levels and distributions of copper in the bubble-containing film. The addition of copper resulted in local changes in layer morphology generated by dissolution of Al_2Cu particles.

The effects of substrate cast microstructure on the growth of anodic oxide layers were evaluated by different microscopy techniques (optical microscopy, laser scanning confocal microscopy, and scanning electron microscopy coupled with energy dispersive X-ray spectroscopy).^[55] In the case of pure aluminum substrate, the insoluble impurities (i.e., Al–Fe and Al–Fe–Si particles) were occluded in the oxide layer. A microstructure consisting of uniform grains and a low amount of insoluble impurities is considered necessary to ensure the growth of sound anodic oxide layers. The microstructure of the binary AlSi_{10} substrate revealed a stronger impact on the morphology of the oxide layers, associated with the presence of Si particles and the morphology of the aluminum cells. In this case, a fine cell structure and a modified morphology of

Si particles were considered favorable for the growth of anodic oxide layers with minimum defects and uniform thickness. Occlusion of Si particles in the oxide layer also affected the morphology of the porous alumina film with the development of deflected pores around the particles.

Iron is generally present in commercial aluminum alloys, either as an impurity or as an alloying element. Such alloys are often surface treated by anodizing, and understanding of the behavior of impurities and alloying elements during the growth of anodic films is of significant importance. In conventional aluminum alloys, as a consequence of the limited solubility, various impurities or alloying elements are often present as second phases, of various shapes, sizes, and compositions. Interfacial enrichment of iron atoms and iron ions has been observed at the alloy/film and film/electrolyte interfaces, respectively during anodizing of Al–7.5 Fe (at %) alloys.^[56] The formation of the anodic oxide involves an initial oxidation of aluminum and enrichment of iron in a layer of alloy, about 2 nm thick, immediately beneath the oxide film. As the level of enrichment reaches the level of about $3.8 \cdot 10^{19}$ Fe atoms/m², corresponding to an average composition of the enriched alloy layer of approximately Al–25 at.%Fe, both aluminum and iron species are incorporated into the film in the presence of the enriched layer. The incorporated iron species, namely Fe³⁺ ions, migrate outward in the growing anodic film, about 2.0 times faster than Al³⁺ ions. Consequently, the iron species eventually reach the film/electrolyte interface forming a thin, amorphous layer probably composed of Fe₂O₃. Oxygen is generated at (or near) the alloy/film interface subsequent to the incorporation of iron species into the film. The general anodizing behavior is similar to that reported previously for an Al–4 at.%Fe alloy, although in the latter case significant oxygen generation and void formation, which limits the thickening of uniform films, is postponed to higher voltages, while the outer, iron-rich layer is composed mainly of crystalline FeOOH.

In cast compositions, silicon and copper are present at relatively large concentrations exceeding their solid solubility in alloy, and therefore are mainly in the form of coarse intermetallic particles. Anodic oxidation of these alloys usually results in the formation of thin, soft, and powdery layers, with a high propensity for “burning” (i.e., local dissolution of the layer and underlying alloy). The coexistence of more than two second phases in the same aluminum matrix (i.e., ternary systems or more) having different anodic behavior presents a challenge to the fundamental understanding of anodizing processes.^[56]

The effect of alloying of aluminum alloys by a wide group of metals on the thickness and micro hardness of PEO coatings was investigated by Nykyforchyn et al.^[57] The composition of the alloys investigated is shown in Table 1.

In the depth of 50 μm, crystalline phases were found consisting of α-, γ-, and δ Al₂O₃, and a Si-containing alloy Al₂SiO₅ was found. As the copper content increases, the

effective thickness of the γ-, β-Al₂O₃ layer decreases. In alloys that contain up to 2.5% of copper beside magnesium, an increase in the magnesium content leads to a decrease in the thickness of the γ, β-phase. At the mass fraction of copper 3.8%–6.7%, the effective thickness of the γ, β-phase increases with increasing magnesium content. Alloying with lithium also increases the coating thickness and particularly improves the microhardness. The thickness of the γ-, β-phase of Al₂O₃ layer exponentially falls with the increasing of copper content in the alloy.

CHARACTERISTICS OF SPARK DISCHARGES

The main feature of PEO is the growth of an oxide layer affected and resulted by large numbers of short-lived sparks (electrical discharges), that completely change the well-known mechanism of anodic oxidation. During a PEO process, spark characteristics determine the thermal and chemical conditions on the oxidizing surface and thus play an important role in the phase formation, structure, and stress state of the ceramic layers that are generated.^[58] Methodologies to obtain quantitative data about PEO discharge events fall into three categories: optical,^[10,14,15,19,59] electrical,^[1,2,60,61] and optical emission spectroscopy (OES)^[17] and are systematized in several publications.^[62,63] Optical measurements are commonly based on the obtaining of images or optical signals at high acquisition rates. They can be used to study the durations (at exposure times on the order of μs), spatial distributions, and apparent spatial extents of discharges. Spectral analysis has the potential to reveal information about the temperatures, densities, and chemical compositions of plasmas. Electrical monitoring is only informative about individual discharges if associated currents can be isolated, so that the signals of separate discharge events do not overlap in time. All the three types of investigation present significant experimental challenges.^[14]

A comprehensive overview of the results of research on the characteristics of spark discharges is presented in the paper,^[15] where electrical characteristics and optical emission spectra exhibited during discharge events in the course of PEO were investigated. Based on these works, the plasma electron temperature was estimated in the range of 4000–7000 K for a unipolar current mode and 4000–5500 K for a bipolar current mode. Gradual change in sizes of microdischarges was established.^[62] At the voltages of 300, 370, and 435 V, discharges have average lifetimes of ~47, ~98, and ~335 ms, respectively. The microdischarges were relatively small at 300 V, with an average size of ~100 μm at 300 V. However, larger microdischarges were formed at 370 and 430 V, with peaks in the size distributions at roughly 200 μm. Smaller microdischarges were also present at the higher voltages. The coating formed at 300 V, after 25 s of microdischarge generation, have pores of typical size ~0.3–0.5 μm; at 330 V, they increased to

~1–2 μm , with a population density of $\sim 5.7 \times 10^9 \text{ m}^{-2}$. Groups of nonuniformly shaped, large pores, up to $\sim 7 \mu\text{m}$ long, with a population density of $\sim 4.3 \times 10^7 \text{ m}^{-2}$, occupied $\sim 5\%$ of the surface were found at 350 V. At 400 V, regions of large pores, up to $10 \mu\text{m}$ long, had extended to $\sim 25\%$ of the coating surface. At higher voltages, large microdischarges were presented at the surface.^[62,64] The current density in discharges rises to $10^9\text{--}10^8 \text{ A m}^{-2}$.

At the typical current density of 1000 A m^{-2} , there occur about 10^9 discharges $\text{m}^{-2} \text{ s}^{-1}$, or about 10 discharges within 1 mm^2 in 10 ms.^[65] The substrate consumption rate of 10 nm s^{-1} corresponds to $10 \mu\text{m}^3 \text{ mm}^{-2} \text{ ms}^{-1}$, so one discharge consumes $\sim 10 \mu\text{m}^3$ of Al (creating $\sim 15 \mu\text{m}^3$ of coating). In terms of energy consumption, this represents $\sim 10^{13} \text{ J m}^{-3}$ of coating, and the local energy dissipated in individual discharges is estimated to be $\sim 100\text{--}200 \mu\text{J}$.^[66]

The pores in the coatings may be formed due to the evolution of gas during the growth and breakdown of the coating. For a $1 \mu\text{m}$ diameter bubble within the coating, equilibrium gas pressures of the order 10 MPa are possible, due to a surface energy of the order 2 J/m^2 for a gas/oxide interface. A front view on the surface of coatings formed in an alkaline solution at different times of electrolysis is presented in Fig. 4.

The results obtained by Yerokhin et al.^[19] also fit the above data. By the analysis of real-time imaging of AC PEO processing on aluminum alloy, the frequency and dimensions of microdischarges were quantified. Small microdischarges with the area 0.02 mm^2 dominate the population throughout the process, the proportion commencing at 96% and falling to 77% at the end point. The percentage of large sparks increase from 0% to 8% at the end point. The medium-sized microdischarge

population is notable, in that it passes through a maximum of 23% during initial stage of coating growth. The microdischarge spatial density decreases from $3.2 \cdot 10^6$ to $7.7 \cdot 10^6 \text{ m}^{-2}$ and the total sample area exposed to microdischarges increases from 3% to 6% (Fig. 5). This implies that larger discharges carry more of the overall discharge current in the later stages of PEO, thus affecting the layer formation. The microdischarge contribution to the coating formation process is evaluated to be 8–10 nm of the thickness increase per microdischarge event. Plasma emission spectra are indicative of there being two distinct regions, a central core of high temperature ($\sim 16,000 \pm 3500 \text{ K}$), with a high electron density ($\text{Ne} \sim 5 \times 10^{17} \text{ cm}^{-3}$), and a peripheral region, probably extending into the surrounding electrolyte, which is much cooler ($\sim 3000\text{--}4000 \text{ K}$) and less dense ($\text{Ne} \sim 10^{15} \text{ cm}^{-3}$). Information has also been obtained about the species present in the plasma. It is clear that there is a complex mixture, incorporating species originating both in the substrate and in the electrolyte^[15] (Fig. 6).

According to the typical emission spectrum obtained from PEO discharges,^[15] strong emission lines were seen for atomic *Na* and *K* (from the electrolyte), *Al* (from the substrate), and also for hydrogen (α and β Balmer lines). It was found^[67] that the plasma temperature obtained from the hydrogen emissions is close to the estimate of 0.3 eV ($\sim 3500 \text{ K}$), wherein the source of hydrogen in the plasma have not been clearly identified.

Activation sputtering of aluminum can be occurring in spark discharges by analogy with cathode glow discharge electrolysis.^[68] As found from the analysis of sparks spectra obtained by OES,^[15,69] the species arisen may be divided into two parts: (1) the species issued from the metal specimen (Al, Mg, and Cu) and (2) the atoms and molecules

Fig. 4 Surface morphology of coatings formed on aluminum in alkaline electrolyte after 3 (a), 6 (b), 9 (c), and 15 (d) min

coming from the electrolyte bath (O, H, OH, and Na). The most intense lines of this group belong to Na and H (Balmer lines Ha and Hh).^[69]

The influence of the frequency of polarization signal on the kinetics of sparks development in time is shown in Fig. 7.^[67] As the process starts, no sparking occurs and the Al line intensity (I_{Al}) stays at zero level. After a short period of time, the breakdown of the oxide layer begins, which is represented by a sharp increase in I_{Al} until a maximum is reached. At that point, I_{Al} starts an exponential decrease with the time. As soon as small sparks have been replaced by greater discharges, the intensity of the aluminum line decreases by, at least, an order of magnitude. Finally, the end of the process is characterized by an aluminum signal close to zero, while the signal of the electrolyte lines becomes very noisy due to the few strong remaining big discharges that appear randomly on the surface. It seems that after a thin oxide layer has grown through electrolytic oxidation, the sparks start to develop leading to localized surface vaporization. Consequently, the density of vaporized aluminum increases as it is observed by OES.

In the course of the processing, the oxide layer becomes thicker. With the film growing, the vaporization of the aluminum is less efficient and the emission intensity of the Al line decreases. The line intensities are greater at 950 Hz than at 100 Hz that may be due to a competition between the repetition rate and the integration time of the optical detector.^[69] However, the observed changes in line intensities are not proportional to the change in operation frequency. This is significant of a modification in the process mechanisms with the current pulse repetition rate. Moreover, the difference in the variation of the characteristic rates of evolution rate of the species according to the frequency can indicate a variation in the growth rate. The largest transition in sparks corresponds to the Mg and Al lines at ~ 280 nm (~ 4.5 eV) with a minimum ionization potential $E_{ion}(Al) \sim 6$ eV.^[15]

The increase in the current density induces a drastic fall in the density of microdischarges on the sample surface.^[70] The number of microdischarges at the surface strongly decreases with the thickening of the layer, and the local current density in microdischarges reach values of several hundred amperes per square centimeter (Fig. 8).^[70]

A synchronization of video recordings with the imposed current also confirms that the discharges can occur only during the anodic cycle of the current. The stages of appearance of discharges were recorded by ombroscopy (Fig. 9).^[70] The delay at about $760 \mu s$ in the appearance of microdischarge after the rising of the anodic pulse current was found in all the experiments. This delay could be directly linked to breakdown mechanisms of the insulating oxide layer. One reason of this delay can be linked to the injection and then trapping the electrons in the layer until

Fig. 8 Rate of discharges during PEO at different current densities (A/m²): 1–1260, 2–2530, 3–3790, 4–6310, and 5–8840^[70]

the channel is formed; the latter causes a local heating of the material leading to the merger. Thus, the delay in the onset of microdischarges corresponds to the time required for the fusion of the material of the discharge channel. This mechanism seems to be predominant at the early stages of the processing, when a barrier layer has only few defects. As the layer grows, it becomes porous and defective. So,

at this stage the delay in sparking corresponds to the time required for the accumulation of charges necessary to reaching the value of a disruptive field.

The observations by ombroscopy highlighted also the evolution of gas bubbles under the effect of microdischarges, without allowing of an accurate determination whether the discharges emerge in the bubbles or whether the bubbles are a result of the discharges.^[70]

A comprehensive study of the nature of individual discharges showed^[71] that they occurred in cascades containing hundreds or even thousands of individual sparks at fixed locations. These cascades affected circular regions, with diameters approximately 100 μ m (Fig. 10).

THERMOCHEMICAL PROCESSES UNDER SPARKS INFLUENCE

Investigations of effectiveness and thermal^[72] balances of PEO in different regimes of electrolysis do not answer a number of questions, such as (a) enormous differences between experimental volumes of anodic gas evolved and those calculated from the point of view of the

Fig. 9 Development of discharges at current density 88200 A/m^2 , recorded at the sampling frequency of 13.2 kHz (the time resolution is 76 μs) at different moments of PEO: 760 μs , 912 μs , and 1824 μs

electrochemical mechanism, (b) extremely large hydrogen content in anodic gases, (c) significant differences in kinetics of hydrogen and oxygen evolution indicating different underlying mechanisms, and (d) the strong relationship between the content of anodic gases and sparking voltages. Large amounts of heat were found^[73] to be generated during the plasma electrolysis. The heat could substantially exceed an input, in some cases it was up to 200% of the input power. In evaluating the heat production, it is necessary to consider whether the heat might have been produced by chemical (rather than electrochemical) reactions.

Unlike for conventional anodizing, the evaluation of the effectiveness of PEO proved to be extremely difficult because of the simultaneous occurrence of electrochemical and thermochemical processes. The electrolysis is always accompanied by intensive gas evolution^[59,74] (Fig. 11) and coating destruction.^[8]

A wide scatter in the data suggests that certain side processes take place on the oxidized surface, the role of which in plasma electrolysis is yet to be understood. Careful determination of the material balance at the metal electrode is therefore required to evaluate the efficiency of the PEO process.

Aluminum is known as the stable metal in contact with oxygen, because of the quick (10^{-5} s) formation of

Fig. 11 Kinetics of the voltage growth (1) and simultaneous gas evolution (2) at current density 935 A m^{-2} in 1 g/L KOH ^[13]

a dense protective oxide layer with the thickness about 100 Å . The dissolution of aluminum in alkaline media produces some amount of hydrogen, but decelerates due to passivation by the reaction products, such as the oxide and hydroxides. Direct hydrogen production is possible at the temperature $\geq 1000^\circ\text{C}$ when the aluminum is powdered^[75]

where Al^* is the activated aluminium, and Q_{Al} is the exothermic heat effect. This heat is determined by the difference between the enthalpy of AlOOH (-985 kJ mol^{-1}) and

of water ($-285.83 \text{ kJ mol}^{-1}$) formation, so the excessive heat $Q_{\text{Al}} = 826.68 \text{ kJ}$ evolves.

Magnesium, which often is a part of the aluminum alloys, exhibits high reactivity to water as well

with a total reaction:

Considering the above, the release of hydrogen from water is possible with the participation of magnesium dihydride MgH_2 and magnesium monohydride MgH . The exothermic heat Q_{Mg} is equal to 354.32 kJ . So, if the content of aluminum in the Al–Mg alloy is 95.5%, 94.0%, and 92.0%, and that of magnesium is 1.5%, 3.0%, and 5.0% mass; correspondently, the heat evolved is 794.79, 787.71, and 778.26 kJ. So, hydrogen evolution is a self-sustaining exothermic reaction, proceeding at a high speed. Moreover, since the heat of reaction of aluminum and magnesium dissolution varies with the magnesium content in the alloy, the total thermal effect of reactions^[27] and^[32] is reduced, resulting in the reduction of the rate of hydrogen release.

Therefore, elaborating a material balance calculated for PEO from the classical electrochemical position, such as for a conventional anodization process, seems to be impossible. Adequate results can be obtained only with accounting of thermal effects and stoichiometry of thermochemical reactions, initiated by sparking. In connection

with those considerations, the particular attention should be focused on bipolar regimes. Electrolysis by bipolar pulses allowed obtaining thin and smooth coatings; however, that fact had no appropriate explanation. At the same time, the hydrogen, evolved in cathodic one-half period by electrochemical reaction, shifts the thermodynamic equilibrium of reactions^[27] and^[32] to the left, thus reducing the aluminum oxide formation.

OES of the microdischarges showed the presence of MgO and MgF fragments issued from the ceramic layer, which confirms the hypothesis of the partial destruction of the layer by the breakdown events (Fig. 12).^[76]

It was shown that the breakdown events take place in the electrolyte impregnated layer with the electron density value of $6\text{--}9 \cdot 10^{15} \text{ cm}^{-3}$. The last statement confirms our idea of possible reactions between ejected metal atoms and water vapor.^[77]

PEO coatings produced on aluminum, in an electrolyte containing KOH and sodium silicate, can readily be grown to thicknesses of $\sim 200\text{--}250 \mu\text{m}$. Depending on the silicate concentration and time of sparking, the coating consist primarily of mullite, alumina, and an amorphous phase.^[9] However, they include an outer (loose) layer, $30\text{--}40 \mu\text{m}$ thick, with a noticeably different microstructural appearance. Moreover, the appearance of this outer layer does suggest that it has effectively been subjected to a series of high temperature annealing treatments, of short duration, but distinguishable from rapid quenching. This might be expected to yield a high proportion of the stable $\alpha\text{-Al}_2\text{O}_3$ phase. It is also significant that a high proportion of amorphous material is detected. A rapid quenching is expected to favor the formation of amorphous phases and $\gamma\text{-Al}_2\text{O}_3$. It would appear that the $\gamma\text{-Al}_2\text{O}_3$ can be converted to $\alpha\text{-Al}_2\text{O}_3$ by the heat treatment to which the outer

Fig. 13 A cross section of the coating formed on aluminum in an alkaline silicate electrolyte after 30 min of PEO. Backscattered Electron SEM image, $\times 1000$

layers are effectively subjected during the violent discharge events, whereas the amorphous material does not transform so readily. It is also possible that the distinct layers are a consequence of different modes of growth within and outside the original aluminum substrate.^[78]

The pressure affected zone around the microdischarge sites on the present coatings extended up to 2 mm. Within this zone, no bubbles of gas were detected, particularly in the immediate vicinity of the microdischarge sites. The gases that might evolve during PEO as products of electrochemical, thermochemical reactions, and local heating may include oxygen, hydrogen, and water steam.^[63] Experiments with ^{18}O tracers demonstrated that the inner (adjacent to the metal) oxide layers of PEO coatings contained no oxygen originating in the electrolyte, and this fact thus far had not been clearly explained.^[79] Measurements of the pore volume have indicated a porosity of about 10% in the inner layer. The pores may be formed due to the gas evolution that accompanies PEO of aluminum.^[79]

Cross sections of coatings reveal that pores and channels are present throughout the coating thickness, with relatively large cavities in some parts of the inner coating (Fig. 13).^[78,80] PEO coatings produced on aluminum, in an electrolyte containing KOH and sodium silicate, can readily be grown to thicknesses of $\sim 200\text{--}250\ \mu\text{m}$. They consist primarily of mullite, alumina, and an amorphous phase.

CONCLUSIONS

Kinetics of PEO of aluminum and plausible mechanisms of the process were discussed. The peculiarities of discharges through the dielectric oxide layer, phenomena occurring during all stages of the vigorous plasma-chemical and electrochemical processing were described. Direct, alternative, and pulse current regimes were analyzed from the electrochemical point of view. Alkaline electrolytes and different

additives (inorganic polymers and dispersed constituents) were discussed in the applicative aspect.

The key role in the appearance and development of electric discharges belongs to the initial stage of oxidation, when a barrier oxide layer is formed. The characteristics of this layer are influenced both by the composition of the electrolyte and the alloy processed, and by the electric mode of polarization of the specimen. The electric regime defines the rate of coating growth and mechanism of charge transfer.

DC, AC, and mixed voltages are used in PEO, and the use of various nonsteady-state modes is becoming very popular. A distinct difference between AC anodizing and DC anodizing is the generation of hydrogen gas on the specimen during the cathodic cycles. Another peculiarity of non-DC PEO processing is the great variety of secondary reactions arising from anion reduction. As is commonly accepted, an oxide layer grows simultaneously both at the metal/oxide and at the oxide/electrolyte interface. Transport phenomena in liquid and plasma phases define the character of this process. Unlike for the conventional anodizing, when the ionic current is the predominant mode of electric charge transportation, electrons are the main charge carriers in PEO.

An alkali is mandatory for the oxidation of aluminum and the formation of an oxide-hydroxide-aluminate layer on its surface. However, the equilibrium between the formation and the dissolution of the oxide layer strongly depends on the presence, nature, and concentration of additives (silicates, phosphates, and other inorganic polymers are most frequently used). The additives make the oxide layer less prone to the attack by the alkali and remain in the layer as its constituents varying its properties.

Different alloying elements (or impurities) play different roles in the process of PEO and the resulting oxide layers. Magnesium causes the formation of two sublayers having different structures and properties. Cathodic (relatively to aluminum) copper and iron may make the oxide layers less uniform. Silicon develops various aluminosilicate phases in the oxide layer.

The most important and the less studied part of the process is formed by various thermochemical and electric phenomena taking place in the sparks, which are the characteristic feature of PEO. Complex chains of acts of melting-solidification, pyrolysis, and phase transformation occur on the scale of milliseconds in sites whose dimensions vary from microns to millimeters and define the final composition, structure, and properties of the oxide layer.

Plasma Surface Treatment: Effects on Mechanical and Corrosion Protection Properties of Hybrid Sol–Gel Coatings

R. Subasri

*International Advanced Research Centre for Powder Metallurgy and New Materials,
Hyderabad, India*

Abstract

Surface cleaning and activation of substrates are two critical processes that affect the mechanical and corrosion resistance properties of protective coatings when deposited on the substrates. Surface cleaning removes the contaminants, for example, grease on the substrate, and surface activation introduces active bonds on the substrate thereby increasing the surface free energy. Conventionally, surface cleaning and activation of aluminum and its alloys are carried out by a wet chemical technique. A convenient and safe alternate to the wet chemical cleaning/activation would be to use plasma for the same purpose. Plasma surface pre-treatment greatly improves adhesion of coatings deposited, which is very vital for good corrosion protection and mechanical properties such as scratch and abrasion resistance. Cold and atmospheric air plasma treatments have been the most widely studied pre-treatments for Al alloys. This article will discuss the advancements in the use of plasma treatment on Al/Al alloys and its effect on corrosion resistance and mechanical properties of coatings deposited after the surface treatment.

Keywords: Adhesion; Aluminum alloys; Coatings; Corrosion resistance; Mechanical properties; Plasma pre-treatment.

INTRODUCTION

Aluminum and its alloys are widely used for industrial applications, due to their low cost, high strength-to-weight ratio, and thermal and electrical conductivity. Al or Al alloys derive their inherent resistance to corrosion due to the natural tendency to form a thin passivating oxide layer. However, this passivating layer is deteriorated in aggressive media, for example, Cl^- containing electrolytes, which results in pitting corrosion. The passive oxide layer can be artificially generated as a thick layer by anodizing. Alternatively, Al alloys can be protected from corrosion by applying protective coatings using silane-based treatments. Silane-based pre-treatments or, in other words, sol–gel-derived coatings are widely used nowadays instead of Cr^{6+} -based conversion coatings. Sol–gel coatings that contain –Si–OH– bonds adhere well with Al alloy surfaces, which have Al–OH bonds, through the formation of –Si–O–Al– bonds. In order to obtain a good adhesion of the silane-based coatings to the substrate, usually, a wet chemical substrate cleaning is carried out. The wet chemical treatment/activation introduces –OH groups on the surface in addition to cleaning the substrate. An environmental-friendly alternate method to the wet chemical surface cleaning method is the use of plasma for surface treatment, which is a dry surface cleaning/treatment technique and obviates the use of strong chemicals like

acids/alkalis. This article presents a brief overview of the effect of plasma surface treatment on the mechanical and corrosion protection properties of coatings deposited over the plasma-treated surface. The different kinds of plasmas that have been investigated for their efficacy will be described initially, following which the effect of treatment parameters, for example, type of plasma used, treatment speed, treatment time, and humidity (in the case of atmospheric air plasma treatment), on adhesion and corrosion protection properties of sol–gel coatings deposited will be discussed. The effect of aging will also be described in brief. Aging effects are important when the plasma treatment technique is implemented in the manufacturing of products, especially in automotive and aerospace sectors.

PLASMA SURFACE TREATMENT ON AL ALLOYS

Al alloys, stainless steel, and Ti alloys are inherently protected from corrosion due to the thin passive oxide layer that is formed on their surface. However, this passive layer loses its protective property when exposed to the aggressive Cl^- ions. Hence, either a thicker and dense passive oxide layer or additional barrier-type protective coatings/paints are required for improving their corrosion resistance property. In the case of anodizable metals,

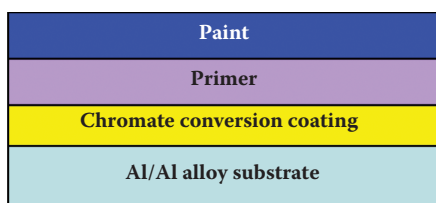

Fig. 1 Schematic showing the configuration of coatings deposited on Al/Alloy substrates prior to paint application

Fig. 2 Schematic showing adhesion between metal substrates and silane-based coatings

like Al/Mg/Ti alloys, the passive oxide layer can also be artificially generated as a thick layer by anodizing or by a method known as micro-arc oxidation^[1,2] to improve the corrosion resistance. In the case of protective coatings/paints, the usual configuration adopted by the industry is to deposit a conversion coating adjacent to the substrate followed by a primer on which a paint top coat is subsequently deposited. A typical configuration adopted for Al alloys is shown in Fig. 1. Hexavalent chromium-based conversion coatings were used earlier, which were subsequently found to be toxic and environmentally less friendly.^[3,4] Hence, use of chromate conversion coatings has now been prohibited globally,^[5,6] and research has been focused towards finding an alternate to replace the hexavalent chrome-based conversion coatings.^[7,8] Sol–gel coatings that contain Si–OH-bonds adhere well with Al/Al alloy surfaces, which have Al–OH bonds, through the formation of Si–O–Al– bonds as shown in Fig. 2.^[9] An untreated Al alloy substrate surface is devoid of active hydroxyl (–OH) groups, which help in forming adherent chemical bonds with the silane-based coating. A generic procedure adopted for cleaning and surface activation of substrates through a wet chemical route comprises the degreasing and alkaline/acid etching steps. It can be clearly discerned that there are several steps involved, and use of acid/alkali makes the surface-cleaning process a cumbersome one. The wet chemical treatment/activation introduces –OH groups on the surface in addition to cleaning the substrate.^[10] However, the wet chemical-induced –OH groups are nonuniformly distributed on the Al alloy surface.^[11] Moreover, use of harsh chemicals such as acid/alkali makes the process, user and environment

unfriendly. Recently, there has been a great interest in the use of plasma for surface cleaning and activation for Al alloys,^[12–26] Ti alloys,^[27] and stainless steel.^[28,29]

Plasma and Its Generation Methods

Plasma is the fourth state of matter. It is an ionized gas containing both charged and neutral particles, such as electrons, ions, atoms, molecules, and radicals moving in random directions. Plasma is created by applying energy to a gas to generate excited species and ions. The source of energy can be thermal, electrical (direct current or alternating current), or electromagnetic radiation (radio frequency with 1.5–50 MHz or microwaves with 0.3–10 GHz).^[20] There are two kinds of plasma, namely, cold and hot. The difference lies in the temperature of the heavy species: It is similar to the electrons (10^4 – 10^5 K) in hot plasma, while it is lower than 773 K in a cold plasma (or nonequilibrium plasma). Cold plasmas are those with $T_e \gg T_{gas}$. They are obtained in low-pressure discharges or in short-pulse discharges as Dielectric Barrier Discharges. Hot plasmas are those with $T_e \sim T_{gas}$. It is produced in plasma torches or in high-pressure discharges. The working pressure of cold plasma is generally lower than that of hot plasma; the production of reactive chemical species takes place at low temperatures. Atmospheric pressure plasma (or AP plasma or normal pressure plasma) is plasma in which the pressure approximately matches that of the surrounding atmosphere.^[30] When compared to low pressure (cold plasma) or high pressure (hot plasma), no reaction vessel is required to maintain a pressure different from that of the atmospheric pressure. The most significant advantage is that integration of an atmospheric plasma treatment system can directly be made in conjunction with any production line.

Interaction of Cold Plasma with Al Alloy Surface

The activity of plasma on any surface of any substrate is two fold; one is to remove the contaminants present on the surface and the other is to increase the surface free energy by creating active bonds such as Al–OH–. Polini and Sorrentino^[17,18,20,22] have extensively studied the effect of cold plasma on aluminum alloys. Cold plasma has been demonstrated to remove the carbon contaminant on aluminum alloys such as AA 2024 and AA 7076 and also improves the wettability of the surfaces,^[20–22] which in turn increases the adhesion of coatings deposited over the treated surfaces. The improved wettability or, in other words, the increased surface free energy has been determined quantitatively through water contact angle measurements after the cold plasma treatment of the surface. Several process variables affect the outcome after the cold plasma treatment, namely, flow rates of the different gases, total pressure in the reactor chamber, substrate temperature and bias, reactor geometry and material,

Table 1 Process parameters varied to study effect of cold plasma treatment on AA2024^[20]

Process variables	Number of levels	Values
Tension (kV)	3	10, 20, 30
Air flow rate (dm ³ /h)	3	15, 35, 60
Treatment time (s)	3	30, 75, 120

Measured surfaces	135	

electrode material and distance between electrodes, and tensioned electric power applied to the plasma. Polini and Sorrentino designed an experimental matrix with few of the process variables shown in Table 1 and studied their effect. The gas pressure is maintained around 1000 Pa. It was found that the supply voltage, air (used in their experiments) flow rate, and treatment time were the main process variables that were found to affect the wettability after the cold plasma treatment, as shown in Fig. 3.^[20] A treatment time of 120 s was found to yield the lowest water contact angle (WCA) of 22.82° when compared to the WCA of 48.31° of the untreated surface. Cold plasma treatment was seen to largely decrease the amount of C and O on the surface, as shown in Table 2. This effect can be largely attributed to the mechanical bombardment of the highly energetic ions from the plasma with the surface and chemical interaction of charged particles with organic contaminants on the surface. Polini and Sorrentino^[17,18] also investigated the possibilities of whether the cold plasma treatment can replace any one or all the steps of cleaning by a solvent, conversion coating, and application of primer and paint, as shown in Fig. 1. The design of experiments that were undertaken is shown in Table 3. Five tests were carried out as per MIL-L-81352 for evaluating adhesion and corrosion resistance of samples generated under various process conditions. Results of adhesion and corrosion tests are shown in Table 4. It could be concluded that cold plasma treatment could, to a large extent, substitute the

Interaction of Atmospheric Plasma with Al Alloy Surface

Atmospheric O₂–He Plasma

Different kinds of atmospheric plasmas have been investigated for surface cleaning and activation of Al alloys for improving adhesion of coatings deposited thereafter. Saleema and Gallant^[16] studied the surface properties of the AA 6061-T6 substrate after subjecting it to atmospheric pressure helium-oxygen plasma and bonding with a bi-component epoxy resin. The adhesive bond strength was evaluated via single lap shear tests on as-prepared specimens as well as on specimens that were exposed to extreme temperature and humidity conditions. Very high adhesion strength of 24 ± 1 MPa was achieved on surfaces after a very short exposure of the He/O₂ plasma for only 15 s under pristine conditions, resulting in cohesive failure of the adhesive itself. Best results were obtained under cataplasma conditions with an adhesion strength of 22.6 ± 1 MPa by introducing a very simple pre-treatment with scotch brite® prior to plasma exposure. Figure 4 depicts the change in contact angle that was obtained as a function of the He–O₂ plasma treatment time. The authors also observed a change in the chemical nature of the surface after the plasma treatment that was verified through Fourier transform infrared spectroscopy (FTIR) analysis. For the surfaces that were treated for a time duration of 15 s, an increased concentration of hydroxyl (–OH) groups was observed, which was evident from the increase in the peak at ~ 3500 cm^{–1}. An increase in intensity of peaks at 1147 cm^{–1} corresponding to Al–OH stretching as well as at 665 cm^{–1} corresponding to Al–O– stretching was also observed. With an increase in the treatment duration, peaks due to adsorbed water increased in intensity between wavenumbers from 1500 to 1650 cm^{–1}. The adhesive bond strength was found to be the maximum (24 ± 1 MPa) for

**Fig. 4** Change in water contact angle as a function of exposure time to He/O₂ plasma^[16]

surfaces that had been treated for a duration of 15 s as compared to untreated surfaces (only 14.5 ± 7 MPa). These results are substantially higher than those obtained for an NaOH-treated surface instead of atmospheric pressure O₂–He plasma treatment.^[10]

Atmospheric Ar–O₂ Plasma

Prysiashnyi et al.^[12] developed an in-house radio frequency plasma pencil using Ar and Ar–O₂ gas mixtures and used it to surface treat pure Al samples. Surface free energies were evaluated based on water contact angle measurements. It was observed that when Ar with a little amount of O₂ was used as the gas to generate the plasma, a rough estimation of the surface oxidation showed that the thickness of the native oxide layer increased from 20 to 60 nm after the treatment. Figure 5 clearly shows that the concentration of the organic contaminants decreases, and there is an increase in the –OH groups on the surface. The authors attribute this to the interaction of the moisture between the surface of Al

Fig. 5 FTIR spectra depicting the effect of plasma treatment of Al sheets, for duration of 3 s, (a) untreated samples; (b) samples treated in Ar flow, and (c) samples treated in Ar with admixture of O_2 with a flow rate of 0.2 l/min^[12]

and plasma jet with the highly reactive oxygen species in the plasma jet. The coatings deposited over the treated surface exhibited no delamination even for increased degrees of mechanical stresses.

Atmospheric Air Plasma

Subasri et al. studied the effect of atmospheric air plasma treatment on the corrosion resistance of hybrid silica-zirconia sol-gel coatings deposited^[23,24] on aluminum substrates. The authors found that the adhesion was substantially improved after the plasma treatment. In addition, they also found that there is a possibility of thickening of the passive oxide layer after the treatment, which further improved the corrosion resistance. Figure 6 shows that the corrosion rate of the coating deposited

Fig. 6 Comparison of corrosion rates for different sol-gel coatings on Al in 3.5% NaCl for 1 h exposure^[24]

over a plasma-treated surface is much lower than that of a bare substrate or the coating deposited over an untreated surface.

Prysiashnyi et al.^[14] studied the effect of humidity on the atmospheric air plasma treatment on Al alloy surfaces. They observed that similar to any other plasma surface treatment, the hydrocarbon contamination was decreased substantially after the atmospheric air plasma treatment. In addition, the treatment in humid air gave rise to $-NO_x$ groups on the surface. Figure 7 shows the aging after plasma treatment in dry and humid air, under different atmospheres. The hydrophobic recovery of the treated surface is due to repeated recontamination from the ambient air. The authors observed that the difference in treatment/storage in dry and humid air to be due to the presence of two states of aluminum oxide depending on the two conditions.

Fig. 7 Change of the total surface free energy (SFE) after plasma treatment in (i) dry air and (ii) in wet air with subsequent ageing in different environments: (a) water, (b) wet air, (c) dry air, (d) vacuum; line (e) represents the values of SFE immediately after plasma treatment in dry/wet air^[14]

CONCLUSION

Plasma surface treatment (whether cold or hot) renders two activities, namely, surface cleaning and surface activation. The organic contaminants are destroyed due to the high energy of the plasma. In the case of atmospheric pressure air/O₂ plasma treatment, active –OH bonds are formed, which help in improving the adhesion and mechanical properties of coatings deposited over the treated surface. A thickening of the passive oxide layer also cannot be ruled out, which further improves the corrosion resistance of coatings. However, an aging effect is also observed once the plasma-treated surface is exposed to the surroundings. The hydrophobic recovery of the treated surface is due to the bonding of contaminants from the surroundings to the surface and hence, plasma treatment is effective when there is no substantial time lag between the surface treatment and post treatment processes in the adhesive bonding/coating/painting industry.

Plastic Flow of Aluminum in Explosive Welding

V. G. Petushkov, M. I. Zotov, and L. D. Dobrushin

E O Paton Welding Institute, Academy of Sciences of the Ukrainian SSR, Ukraine

Abstract

Joining of metals in explosive welding takes place as a result of their plastic deformation during a high speed collision and is usually accompanied by typical formation of waves at the interface. In welding aluminium, the weld boundary can also be straight if the speed of the contact point is v_c is ≤ 1900 m/s. These welding conditions make it possible to prevent melting of the metal at the interface and increase at the same time its corrosion resistance. In this article, the effect of the dynamic collision angle on the special features of plastic flow of the metal in the vicinity of the contact boundary in welding sheets of AS5 aluminium is described.

Keywords: Cladding; Explosive welding; Fused regions; Microstructure; Plastic deformation.

Joining of metals in explosive welding takes place as a result of their plastic deformation during a high speed collision and is usually accompanied by typical formation of waves at the interface. In welding aluminium, the weld boundary can also be straight if the speed of the contact point $v_c \leq 1900$ m/sec. These welding conditions make it possible to prevent melting of the metal at the interface and increase at the same time its corrosion resistance. For example, repair of the reaction vessel of an autoclave constructed for producing concentrated nitric acid,¹ by cladding welded joints with a protective layer of technical aluminium, increases corrosion resistance and, correspondingly, the service life of the autoclave by a factor of 5–6.

In this work we examined the effect of the dynamic collision angle γ on the special features of plastic flow of the metal in the vicinity of the contact boundary in welding sheets of A85 aluminium. The thickness of the cladding sheet was $\delta_1 = 4$ mm, that of the clad substrate $\delta_2 = 25$ mm. The surface roughness of the welded sheet was $R_z = 4 \mu\text{m}$. The welding conditions are given in the Table.

Figure 1 shows the microstructure of the welded joint produced at $\gamma = 19^\circ$. It can be seen that at distance $R = 1$ mm from the boundary of the joint the cladding sheet contains local areas of fused metal with length $l_f = 0.07$ – 0.15 mm and area $S_f = 0.002$ – 0.8 mm², which alternate with regions without fusing and microcavities with length $l = 0.2$ – 0.6 mm. The grains of metal in the vicinity of the boundary of joint II and the boundary with fused region I are greatly deformed in the direction of movement of the contact point. At $\gamma = 10$ and 40° there is no melting of metal at boundary I. According to the hypothesis proposed in Ref. [2], fusing of the metal at a high speed collision is caused by “capture” of the cumulative jet. Taking into account the classification proposed by these authors, the type of joints produced in this work corresponds to the stationary cumulation regime

(without “capture” of the jet), but the presence of fused metal in layers away from the contact surface of the welded sheets contradicts this hypothesis.

Experiment No.	Initial welding parameters		Kinematic parameters of collision			
	$\alpha,^\circ$	r	$\gamma,^\circ$	$v_r, \text{m/sec}$	$v_t\tau, \text{m/sec}$	$v_c, \text{m/sec}$
1	0	0.33	10	328	29	1800
2	0	1.48	14	440	54	1800
3	14	0.31	19	590	170	1800
4	16	0.31	21	590	190	1600
5	27	0.31	32.0	590	292	1100
6	39	0.31	44.5	590	396	850

Comment. Here α is the initial angle; r is the ratio of the mass of the charge to the mass of the flyer sheets; γ is the collision angle; v_r is the collision speed; $v_t\tau$ is the tangential component of the collision speed

Analysis of the distribution of microhardness of the metal in the vicinity of the contact boundary (Fig. 2) shows that, with γ increasing from 10 to 19° , the thickness of the layer of the metal of the clad base included in the plastic flow decreases. Examination of the diagram of collision of the flyer sheet with the clad base (Fig. 3) makes it possible to determine the tangential component of the collision speed from the equation

$$v_{tr} = v_r \sin\left(\alpha + \frac{\beta}{2}\right) \quad (1)$$

With an increase of γ the above speed rapidly increases (see the Table). This results in extensive displacement of the surface layer of the metal of the cladding sheet in relation to the collision point at the contact boundary with a speed close to $v_t\tau$. Thus, after the start of contact between the welded sheets,

Fig. 1 Diagram and microstructure ($\times 250$, $2/3$ reduction) of welded joints in A85 + A85 aluminium: R) Depth of zone of intensive plastic deformation; I, II) Boundaries of region of intensive plastic deformation in the metal of the cladding sheets; δ_1, δ_2) Thickness of the metal of the cladding and clad sheet

Fig. 2 Distribution of microhardness in vicinity of the contact boundary of the A85 + A85 joint: 1) $\gamma \approx 10^\circ$, $v_t \tau = 29$ m/sec; 2) $\gamma \approx 19^\circ$, $v_t \tau = 170$ m/sec

Fig. 3 Diagram of particle flight

the upper sheet continues to move, causing plastic flow in the layer whose thickness in this case is equal to a quarter of the thickness of the upper sheet (Fig. 1). Plastic flow is characterized by steep gradients. The high shear strains developed as a result of this process at boundary I lead to intensive heat generation (as indicated by Fig. 1 the intensity of this regeneration is higher than at contact boundary I), and this also causes local fusing of the metal. A reduction of the speed of the contact point ($v_c \leq 1700$ m/sec) reduces the intensity of plastic flow and prevents fusing of the metal.

At $v_c \approx 1000$ m/sec lack of fusion defects form at the boundary of the joint, and at $\gamma = 44.5^\circ$ the cladding sheet fails (by shearing) in its double bend section (prior to collision with the clad base). It can be assumed that the depth of the plastic flow zone of the metal of the clad base under these collision conditions decreases to its critical value and, consequently, the joint does not form.

The results are in satisfactory agreement with the data published in Ref. [3] and explain the relationships of formation of high quality joints with a straight profile of the contact boundary.

CONCLUSIONS

1. In explosive welding sheets of A85 aluminium at $\gamma \geq 19^\circ$ the metal of the cladding sheet contains a boundary with fused sections positioned at a distance from the boundary approximately equal to a quarter of a sheet thickness. With a decrease in v_c the amount of fused metal in these sections decreases.

2. With increasing γ the depth of the zone of plastic flow of the metal of the cladding sheet remains constant and that of the clad base decreases.
3. It is evident that the formation of the boundary with fused regions is explained by intensification of the displacement of the cladding sheet in relation to the collision point caused by the large increase of v_f with increasing γ .

Polyphase Eutectics of Aluminum Alloys: Effect of Phase Composition

Malgorzata Warmuzek

Laboratory for Structure Analysis and Mechanical Testing, Instytut Odlewnictwa w Krakowie (Foundry Research Institute), Zakopiańska 73, Kraków, 30-418, Poland

Abstract

The polyphase eutectics (α -Al+intermetallic+Si) constituting the final aluminum alloy microstructure were characterized by their phase composition, growth mechanism, and morphology of eutectic crystals. The main groups of eutectic phase constituents were presented with a special attention paid to intermetallic phases. Morphology of different types of polyphase eutectics, among those divorced, was characterized and presented (as microscopic images) on microphotographs. The microstructural effects of stable and metastable phases competition in the stage of nucleation and growth of polyphase eutectics as affected by local cooling rate and liquid alloy composition were described. Some examples of the evolution of the phase composition of eutectics in commercial alloys due to modifications of technological procedures were presented.

Keywords: Aluminum alloy; Eutectic; Microstructure; Phase constituent; Solidification path.

INTRODUCTION

The microstructure of the multicomponent aluminum alloy is composed of dendrites or grains of α -Al solid solution and other crystalline phases of different chemical composition, crystal structure, morphology, and physical properties. The main phase components of alloy microstructure are crystals of composed solid solutions, pure components (such as Si), and intermetallic phases. Description of the solidification path of such a complex system is usually based on the simplest systems, binary, ternary, or quaternary, using the model of the directional solidification.

The processes of microstructure formation in multicomponent aluminum alloys, of more than two components, are less unequivocally identified than those for binary, especially for composed sequences of the polyphase reactions in the residual liquid.

A sequence of many different phase transformations, congruent, incongruent, eutectic and peritectic, of different freedom degrees, invariant, monovariant, bivarient, or polyvariant, occur in the multicomponent alloy solidification path. Temperature range of these transformations is often very close each to other, so the particular microstructure effects are difficult to differentiate.

The actual solidification processes that are expected in the industrial practice can be realized through different ways. Some of equilibrium processes can be avoided because of kinetic limitations; therefore, metastable or nonequilibrium phases appear in the alloy microstructure. In the last stage of the solidification process, the eutectic reactions are kinetically

privileged with respect to peritectic reactions running slower in such conditions.^[1,2] Thus, polyphase eutectics are the main constituents of the final aluminum alloy microstructure in the interdendritic microregions (Fig. 1).

In the technical aluminum alloys, the products of eutectic reactions fill the space of interdendritic microregion sometimes reducing the shrinkage porosity. They form a tough, brittle network that rounds the soft dendrites of α -Al solid solution. Two general parameters that characterize the interdendritic eutectic are important from technological point of view: its volume fraction V_T and solidification temperature. In the heat-treatable wrought alloy, the temperature of the last interdendritic solidification limits the homogenization conditions. The volume fraction, type, and morphology of the interdendritic eutectic phase constituents also determine alloy properties such as tensile and crack resistance, fracture toughness,^[3] corrosion resistance,^[4] tightness and porosity,^[5] recrystallization course,^[6] quality of the anodized protection,^[7] and rollers galling during hot rolling.^[8]

Total volume fraction V_T of the interdendritic eutectic formed in the real solidification processes is composed of two fractions: equilibrium (V_e) and nonequilibrium (V_{ne}).^[9]

$$V_T = V_{ne} + V_e \quad (1)$$

However, nonequilibrium fraction (V_{ne}) of eutectic can have equilibrium, metastable, or nonequilibrium phases.

This proportion depends on the cooling rate, α -Al dendrites dispersion (as value of SDAS—Secondary Dendrite

Fig. 1 Interdendritic microregions of the Al alloy microstructure with polyphase eutectic: (a) hypoeutectic cast AlSiNiCu alloy and (b) wrought AlSiMg alloy, in as-cast state, etch.1%HF, LM

Table 1 Solubility of the main alloy components in liquid aluminum and in α -Al solid solution^[10–13]

Element	Temperature (°C)	Solubility limits (wt%)			Concentration range of components in commercial alloys
		In liquid alloy	In α -Al solid solution	In α -Al solid solution (25°C)	
Si	577	12.6	1.65	0.008	0.006–13.0

Mg	450	35.0	14.9		0.05–10.6
Zn	381	95.0	82		0.05–7.0

Arms Size), and nonequilibrium microsegregation effects. During subsequent stages of microstructure formation, either cooling below solidus or heat treatment, further microstructure evolution occurs: nonequilibrium fraction of equilibrium phases can dissolve, and metastable phases transform into equilibrium ones.

Contents of the alloying elements in commercial aluminum alloys determining eutectic volume fraction and its phase composition vary in a wide range (Table 1). Although the solubility limit of some components at solidus temperature is relatively high (Cu, Mg, Mn, Zn), usually it drops very quickly to a very small value at room temperature. The equilibrium limits of solubility are very often exceeded because of the nonequilibrium microsegregation of alloy components; thus, in the interdendritic microregions, microstructural complexity appears.

MULTICOMPONENT PHASE CONSTITUENTS OF INTERDENDRITIC EUTECTICS

Classification of Condensed Phases in Metal Alloys

The condensed crystalline phases in the conventionally crystallized metal alloys are classified according to the homogeneity of chemical composition and the order of

crystal lattice. Therefore, in the alloy microstructure, the crystals of the solid solutions, those of pure components and intermetallic phases are present. Complex chemical composition of the alloy does not have to introduce the microstructural complexity in the solid state because in some circumstances the disordered solid solution might remain more stable than ordered intermetallic compound (Fig. 2a). The morphology, i.e., habit of the crystals formed from the liquid alloy, depends on the characteristic of the crystal lattice and mechanism of crystal growth.^[1,14] In the early stage, before the solidification begins, the short range order of atoms has been revealed in the eutectic melt, as a result of the tendency to form the clusters connected with glue atoms: [cluster Al+cluster B].^[15–18] The characteristic of the liquid alloy structure in Al-Cu and Al-Si binary systems reveals the difference in the further microstructure effects. In the Al-Cu eutectic melt, besides Al-Al clusters, the presence of chemically ordered Al-Cu groups of atoms was revealed, which were considered as possible precursors of the intermetallic compound Al_2Cu .^[16] As it was stated in the works of Shtablayvi et al. and Mudry et al.,^[15,16] the Al-Si eutectic melt consisted mainly of clusters containing the same kind of atoms Al-Al or Si-Si, while the tendency to form clusters between Al and Si atoms was negligible.

Empirical Hume-Rothery (H-R) rules give some indications for predicting crystalline structure of the condensed phase, i.e., preference for either substitutional solid

Fig. 2 Thermodynamical and geometrical factors governing alloy structure: competition between solid solution and intermetallic phase in chosen binary systems based on Al (a)^[21] and phase map of the microstructure of multicomponent alloys (geometrical factor $\delta = [\sum c_i (1 - r_i/r)^2]^{1/2}$, where: c_i —concentration of the component i , at.%, r_i —atomic radius of component i , and r —average atomic radius in alloy; thermodynamical factor $\Omega_s = T_m \Delta S_{\text{mix}} / \Delta H_{\text{mix}}$, where: T_m —temperature of melting, ΔS_{mix} , ΔH_{mix} —entropy and enthalpy of mixing, respectively, S —solid solution, I —intermetallic, $S + I$ —solid solution and intermetallic, and B —amorphous alloy (b)^[22]

solution or ordered intermetallic compound,^[19–24] such as ratio of the atomic radii ($r_A/r_B < 1.0$ – 1.14), difference in the electronegativity and similarity of crystal structure of the system components.

These criteria have been verified by the new theories of predictions of the multicomponent metal alloys' stability, however recently additional criteria were introduced to form the alloys microstructure maps, taking into account both thermodynamic and some Hume-Rothery assumptions, as it is presented in Fig. 2b.

Multicomponent Phase Constituents of Polyphase Eutectics in Aluminum Alloys

Solid Solutions

The α -Al solid solution is a phase constituent of most of the polyphase eutectics solidifying in the interdendritic microregions. It is a disordered substitutional solid solution, i.e., the atoms of alloying additions take random sites in the crystal lattice of Al. This solution can have all alloy components dissolved in it. Atoms of additional elements that remain built in Al crystal lattice cause solid solution hardening of alloy matrix, while those being in excess form dispersive precipitates additionally strengthening alloy matrix. Another solid solution that presents as the eutectic constituent in aluminum alloys is formed on basis of the Zn crystal lattice, and it contains a large amount of Al (Table 1).^[10]

Intermetallic Phases

Intermetallic phases constitute a unique class of metallic materials with characteristic long-range ordered crystal structures formed below their melting point (T_m) or critical ordering temperature (T_c).

The specific features of intermetallic phases as alloy microstructure constituents of specific morphology and size are as follows:^[19–25]

- Symmetry of crystal lattice.
- Chemical composition.

The specific physical properties of the intermetallic phase, such as thermal and electrical conductivities, depend on the kind of interatomic bonds and crystal lattice symmetry, while its corrosion resistance depends mainly on its chemical composition. Interatomic bonds in the intermetallic phases are heterodesmic; besides the metallic bonds (weak), strong covalent or ionic bonds are present. The presence of strong covalent bonds generates special material effects such as hardness, yield strength, and fracture toughness, which is different from those of metal solid solutions, despite containing the same components.

The proportion between metallic and covalent bonds strongly determines macroscopic properties of intermetallics, such as Poisson's ratio and Young's modulus. The enthalpy of formation of intermetallic compound is related to the kind of bond: ionic, 125–500 kJ/mol; covalent, 40–500 kJ/mol; and metallic, 100 kJ/mol.^[19–24]

The quantitative relations among components concentrations are characteristic for intermetallic phases. Depending on the range of chemical homogeneity, two groups were formed: the first one of stable value of concentration relations and the second one of a wider range of homogeneity (Fig. 3).

Three of the most common superlattices occurring in binary intermetallic phases are the B2 type (or CsCl type), the L10 type (or AuCuI type), and the L12 type (or Au3CuI type). The specific relations among components concentrations reflect the order of atoms in the crystal

Fig. 3 Binary equilibrium phase diagram—different alloy microstructure constituents are present: solid solution α , pure component B , intermetallic phase of stoichiometric composition $A_{n1}B_{m1}$ (line compound), and intermetallic phase nonstoichiometric composition γ

lattice. In most of the intermetallics present in the aluminum alloys, the atoms of components are ordered in specific sublattices, mainly such as {Al, Si atoms} and {metal atoms}.^[26] In both of these sublattices, the vacancies are also present. In each of the sublattices mentioned earlier, the mutual replacement of atoms in the sites filling takes place very often, mainly between the atoms of elements ascribed to each of them: e.g., $\text{Al} \leftrightarrow \text{Si}$, $\text{Fe} \leftrightarrow \{\text{Mn}, \text{Ni}, \text{Cr}\}$, $\text{Zn} \leftrightarrow \text{Cu}$, and between atoms and vacancies. The permissible range of the chemical homogeneity is determined by the thermodynamical stability of phase crystal structure.^[19,25,26]

The intermetallic phases present in the aluminum alloys usually belong to one of the three groups presented in Table 2. General criterion of the crystal lattice stability, thereby the stability of the phase component of the polyphase material, is a very important factor of material microstructure forecasting.^[19,23–25]

In the electron phases, the specific value of e/a factor, characteristic for the electronic configuration of atoms in the elementary cell, determines the stability of crystal lattice. The stabilization of the structure of the electron phase achieves the maximum when the Fermi sphere of diameter k_F touches a prominent Brillouin zone of diameter K_B : $2k_F \approx K_B$.^[19,23,24]

It was assumed that in the Al-TM systems (TM—Transition Metals), AlTM aluminides, so-called spd intermetallic phases, are characterized by a very strong sp–d hybridization, between the sp states of Al atom and the d orbitals of the transition metal atom. The stabilizing value of the electron factor e/a was established for some of the crystal lattices of these phases such as for A1 lattice, $1 < e/a < 1.38$; for A2, $e/a < 1.48$; for complex structures with 52 atoms per unit cell, $e/a < 1.62$; and for A3, $e/a \approx 1.75$.^[23,24] In the crystal structure of the electron phase of the spd type, reproduction of two kinds of the icosahedra was revealed:

Table 2 Intermetallic phases in aluminum alloys^[19,22–25]

Phase		Components	Crystal structure stabilization factor
Electron phases	spd	1. Transition metal: Ti, V, Cr, Mn, Fe, Co, Ni 2. Al or Al and Si	Electron density: e/a Size factor: $r_A/r_{B<0.15}$ Electronegativity
	other	1. Noble metals: Cu 2. Metals: Be, Mg, Zn, Cd, Al, Ca, Ga, In, Ge, Sn, Sb	
Laves phases	AB_2	1. Metal of higher atom radius r_A 2. Metal of less atom radius r_B	Size factor $r_A/r_B = 1.225$ Chemical composition $C_A/C_B = 2$

a simple icosahedron in the center of the elementary cell face and a double one on the cell's edge. In these phases, there are no direct bonds between TM atom pairs. The coordination of TM atoms in the crystal structure depends on their atomic numbers.^[23,24,26–28]

The Laves phases belong to the class of topologically close-packed (TCP) structures, named Frank–Kasper phases. They are the size-factor compounds in which the relative sizes of the atoms are important in determining the structural stability. They have the general composition AB_2 .

The closest packing of hard spheres ascribed to A and B atoms is obtained for the radius ratio $r_A/r_B \approx 1.225$. It was reported that in the multicomponent aluminum alloys, the value of r_A/r_B ratio varies from 1.05 to 1.68.^[25,29–32]

Since the observed value of the enthalpy of formation of these phases varies over a wide range from 0 to approximately -250 kJ/mol, mixed atomic bonds are possibly present: metallic, covalent, and ionic.^[22,25] Among the Laves phases, three groups of structures were differentiated: the cubic face-centered C15 ($MgCu_2$), hexagonal C14 ($MgZn_2$), and mixed double hexagonal C36 ($MgNi_2$), differing by the particular stacking of the same four-layered structural units. The coordination number was reported to be equal to 16 (4 A and 12 B atoms) for A atoms and 12 (6 A and 6 B atoms) for B atoms. In some of the Laves phases with transition metals, other stabilizing factors such as electron density (e.g., in C14, $e/a = 1.8–2.32$; in C15, $e/a < 1.8$; and in C36, $e/a > 1.8–1.95$) or difference in electronegativity may also play an important role.^[29,32]

The specific phases of giant elementary cells, named Bergman and Samson phases, are present in some aluminum alloys as eutectic constituents.^[33,34]

The Bergman phase $Mg_{32}(Al, Zn)_{49}$ (T phase) is present in the Mg–Al–Zn system. Its cubic cell geometry is based on a periodic arrangement of the icosahedral Bergman clusters. Connections between the clusters are formed by “glue atoms”; there are Al and Zn atoms, but not Mg. However, high structural complexity of the Bergman phase does not result in high complexity of its electronic structure.^[33] The Al–Mg system contains Mg_2Al_3 phase (Samson's phase). The cubic unit cell is huge: it contains 1832 possible atomic positions, but many of them are simply unoccupied. Thus, in fact, only 1168 positions are fully or partially occupied.^[34]

Intermetallic Phases in Interdendritic Eutectics Microstructure

In Table 3, characteristics of the crystal lattice of the intermetallic phases that are formed through invariant eutectic reactions in the multicomponent aluminum alloys are present.

However, most of the intermetallic phases present in the binary and ternary systems exist in a wide range of

homogeneity (Table 4). It reflects the atoms replacement in a limited range, sometimes with occupation of vacancy sites.

In the multicomponent Al-based systems, some of the intermetallic phases form continuous arrays of the isomorphous solid solutions. They form by subsequently replacing the atoms in the crystal lattice (sublattice) without any change in its symmetry. Some changes in the elementary cell parameters are noticed due to difference in the atomic radius of replaced components. The most recognized are the arrays between the pairs of systems:^[10–13]

- AlMgZn and AlMgCu: $Al_2Mg_3Zn_3$ – $AlZnMgCu$ – Al_6CuMg_4 , $MgZn_2$ – $AlZnMgCu$ – $AlMgCu$, $MgZn_5$ – $AlZnMgCu$ – $Al_{10}Cu_7Mg_3$.
- Al–Fe and Al–Mn: Al_6Fe – Al_6FeMn – Al_6Mn .
- Al–Ni and AlNiCu: Al_3Ni_2 – Al_3CuNi .

MICROSTRUCTURE CHARACTERISTIC IN INTERDENDRITIC MICROREGIONS

Classification of Eutectic Phases Morphology

Crystallization of the interdendritic eutectics is preceded by solidification of primary α -Al solid solution. Binary eutectic reaction $L_1 \rightarrow \alpha\text{-Al} + \beta$ (where β - second eutectic phase, intermetallics, pure elements) starts in the residual interdendritic liquid when specific composition and temperature, defined by the coordinates ($T = T_E$, $C = C_E$), are reached. At the temperature $T < T_E$, the mixture of two solid phases $\alpha\text{-Al} + \beta$ becomes thermodynamically privileged in respect of the liquid. As was stated in the works of Hume-Rothery and Anderson and Ma et al.,^[56,57] the binary eutectic frequently forms at near-simple composition ratios such as 8/1, 5/1, 3/1, 2/1, and 3/2. The phase equilibrium diagram reveals the kind and number of phases constituting eutectic, depending on the chemical composition of the alloy. However, in the real alloy, the morphology of the eutectic phase crystals and their relative distribution are important parameters for the microstructure description.

The general classification of binary eutectics is based on the morphology of its phase constituents determined by the topography of the growth front. Thus, the base of the general classification is the value of the entropy of melting ΔS_m of the eutectic phases. Depending on the ΔS_m value, three groups of eutectic were formed:^[1,58–63]

- Regular eutectics: non-faceted–non-faceted, for both phases $\Delta S_m < 23$ J/(mol·K).
- Irregular or complex regular eutectics: faceted–non-faceted, for one phase $\Delta S_m > 23$ J/(mol·K), and for the second phase $\Delta S < 23$ J/(mol·K).
- Irregular eutectics: faceted–faceted, for both phases $\Delta S \geq 23$ J/(mol·K).

The shape of eutectic phases in the regular eutectic usually is determined by the value of volume fractions ratio ζ of both phases. Thus, they form a shape of lamellae ($\zeta > 0.32$) or rods ($\zeta < 0.32$ or 0.28).^[1,58,62] The second criterion of the eutectic classification is its growth

Table 4 The range of homogeneity in chosen intermetallic phases^[10–13]

Phase	Range of concentration (wt%)
Al ₂ Cu	Cu: 52.5–53.9

mechanism: coupled or divorced. In aluminum alloys, different types of eutectic classified according to general rules can occur; however, in the chosen microregions, not typical mixtures of different type of phases can be recognized (Table 5).^[1,62,63]

In multicomponent alloys, the microstructural patterns that form during solidification are far more complex than the lamellar and rod types, generally observed in binary eutectics (Table 5). The formed patterns of eutectic phases depend on such factors as^[1,58–63,65,66]

- Actual temperature conditions in the solidifying microvolume of the liquid.
- Volume fractions of eutectic phases.
- The diffusion coupling in front of each phase.
- Interfacial energies at triple point, determined by crystal lattice anisotropy.

The morphological regularities of the eutectic phases observed in the directionally crystallized alloys were ascribed to the specific mechanism of their formation through, so-called, cooperative (coupled growth). In the polyphase interdendritic microregions, the general rules of cooperative growth concern probably only very small

Table 5 Types of eutectics morphology in the multicomponent aluminum alloys

Eutectic	Binary system		Multicomponent system	
	Non-faceted–Non-faceted	Non-faceted–faceted	Faceted-faceted	Divorced
Phase	Solid solutions: α -Al/Zn(Al)	α -Al/Si, α -Al/Intermetallic phase	1. Si/Intermetallic phase 2. Intermetallic phase 1/intermetallic phase 2	Non-faceted–Faceted: α -Al/Si/Intermetallic phase Non-faceted–Faceted: α -Al/Si/Intermetallic phase 1/Intermetallic phase 2

Fig 4 Polyphase eutectics in the interdendritic microregion: locally quasi-coupled (a) binary eutectic (α -Al+M-AlZnMgCu), etch.1%HF, LM; (b) binary eutectic (α -Al+Al₆FeMn), deep etch, SEM;^[64] (c) quaternary, eutectic (α -Al+Al₂Cu+Al₈FeMg₃Si₆+Si) etch.1%HF, LM; and (d) polyphase divorced eutectic (α -Al+Al₂Cu+Al₈FeMg₃Si₆+ β -AlFeSi+Si), etch.1%HF, LM

microvolumes. However, microscopic observation and local analysis of the chemical composition and crystal lattice identification are useful tools for the description of the microstructure state. For example, on the microstructure images, in which some regularities are described by the models of the coupled growth, such a stage of branching characteristic for interlamellar distance stabilization in the Jackson–Hunt model^[62] can be identified (Fig. 4a,b).

Morphological forms, named as chained brick-like or cobblestone, observed in the ternary α -Al+Al₂Cu+Al₂Ag eutectic, described in Refs. [67–69], can be also recognized locally in the quaternary eutectic (α -Al+Al₂Cu+

Al₈FeMg₃Si₆+Si), in the technical hypoeutectics AlSi6Cu3 alloy (Fig. 4c).

Nucleation of the Eutectic in the Interdendritic Liquid

The different mechanisms of the initiation of the coupled growth of the two-phase eutectic cell ($\alpha + \beta$) in the hypoeutectic alloy were revealed: either nucleation at the solid/liquid (S/L) interface of the primary phase or at few points between the branches of the primary phase dendrites, along liquid grains boundaries.^[63,69,70] In the hypoeutectic Al alloys, the nucleation of the (α -Al+ β)

eutectic cell takes place mainly at α -Al dendrite tips and usually starts from the formation of the nucleus of the α -Al phase. However, the differences in the nucleation driving force depend on the nucleation undercooling of both phases; thus, the actual nucleation temperature will decide the nucleation sequences of the eutectic phases. In the Pb-Sn system, Sn nucleates with difficulty from the melt and then becomes an efficient nucleant for Pb. On the other side, although Pb can nucleate with rather low undercooling, the additional undercooling of the liquid alloys is necessary to form Sn nuclei. In the Al-Si system, the α -Al solid solution nucleates at the Si substrate in the liquid alloy undercooled to 25 K below the equilibrium eutectic temperature T_E , while Si nucleates at the Al substrate when undercooling is equal to 18 K. Although this difference is not so important, it creates some preference for Al crystal to initiate Si crystal nucleation. In the Al-Al₂Cu eutectic, the α -Al solid solution nucleates at the Al₂Cu substrate in the liquid alloy undercooled to 7 K below the equilibrium eutectic temperature T_E , while Al₂Cu nucleates at the Al substrate when undercooling is equal to 13 K. The ratio of the nucleation temperatures of both phases favors the Al₂Cu phase to initiate the coupled growth.^[1] Nuclei formation depends also on the wettability of its surface by liquid alloy because the wetting function value determines the critical radius of nuclei. However, in the multicomponent alloys, the surface energy and nucleation temperature of the particular eutectic phases are not known exactly; thus, the general model of this phenomenon was not elaborated yet.

Growth of Eutectic Phases

The mutual nucleation of eutectic phases is necessary to continue their growth in the cooperative mode leading to formation of more or less regular morphology of the particles of both eutectic phases. If the nucleation of eutectic phases occurs separately, without direct contact, the divorced eutectics will form. Then, each of the eutectic phases grows independently, and its morphology is not subordinated to relations governing their coupling.^[1,63] It is typical mode for hypoeutectic Al alloys with polyphase (α -Al+ β + γ) eutectics, in which common interface between phase constituents very often does not exist.

The interlamellar distance λ is the main parameter of the lamellar eutectic composed of plates or rods of both eutectic phases. In the regular eutectics, either rods or lamellar, the stable λ value was established based on the Jackson–Hunt theory: $\lambda v_R^n = \text{const.}$, as governed by growth process conditions, i.e., alloy composition and actual undercooling at S/L interface. However, it was observed that even at stable growth conditions, instabilities of the interlamellar distance can appear and then develop. Cooperative growth may be continued under condition of limitation of the λ value deviations in a range of acceptable values: maximum λ_M and minimum λ_m . This range

represents locally established effect of the competition between two tendencies: to decrease the solute diffusion distance between plates of both phases and to decrease the interface α/β energy. Irregular eutectics exhibit larger undercooling and the interlamellar space λ value than those predicted by the Jackson–Hunt theory. This disagreement was attributed to the fact that irregular eutectics grow at a non-isothermal interface S/L.^[71,72] Processes of growth of the eutectic phases in the interdendritic microregions in the technical conditions cannot be simply described by the Jackson–Hunt theory.

Eutectic crystallization model related to binary systems solidifying directionally under strictly controlled conditions can be applied only in a very limited range for description of the processes in the interdendritic microregion of the multicomponent alloys. All the data necessary to describe possible interactions between atoms of components in such systems are not known. Furthermore, even a small addition of ternary component can destroy the regularity of the eutectic solidification front and phase components morphology.^[68] Nevertheless, an initial description of these phenomena might be approximate by directional solidification analogy.^[61,66–68,73–75] Some extension of the Jackson–Hunt theory was applied for the ternary alloys AlCuAg^[61,73] and AlNbNi^[74] to consider the evolution of lamellar morphology depending on changes of cooling conditions or an addition of third components. The observed instability developed along the plates was ascribed to the interplay between the destabilizing effects of the impurities on the local change in lamellar spacing on the front motion. Mechanism of stabilization of interparticle distance by branching or overgrowth proposed for binary eutectics seems to be efficient for the ternary eutectics in 3D space only for rods. In the ternary lamellar eutectics, only the nucleation of the new lamellae was considered as a factor of the interlamellar distance λ stabilization.^[76]

The morphology of eutectic phases observed in the multicomponent systems is always too complicated to be classified with the simple criteria mentioned earlier. Polyphase microregions contain different phases, which represent their own morphology, and not subject to cooperative growth rules. The general morphological classes of eutectic phases, lamellae, fibers, rods, broken lamellae, spirals, or globules, are often insufficient to describe observed shapes of the eutectic phases, especially for divorced eutectic, the most frequently formed in the residual liquid microregions. Therefore, a lot of other names are also used, such as plates (Fig. 1a), dendrites (Fig. 5a), blocky (Fig. 4d, 5b–d), Chinese scripts (Fig. 1b), fish bone (Fig. 4b), feathers, branches (Figs. 1a, 4d), or needles (Fig. 4d). In addition to these, some intermetallic phases, such as Al₂Cu, can have a different shape in eutectic microregions (Fig. 5). Morphological evolution was also observed depending on the modification of the crystallization conditions by magnetic field^[76] or during sintering.^[77]

Fig. 5 Morphology of the particles of Al_2Cu phase: irregular plates and blocky particles in binary eutectic $\text{Al}_2\text{Cu}+\alpha\text{-Al}$, in the hypoeutectic AlCu alloy, LM (a), SEM (b), and blocky particles in the polyphase eutectic $\text{Al}_2\text{Cu}+\alpha\text{-Al}+\text{Si}+\text{Mg}_2\text{Si}+\beta\text{AlFeSi}$ in the commercial AlSi6Cu4 alloy, LM (c), SEM (d)

Fig. 6 Morphology of phase constituents in the polyphase eutectics; (a) partially coupled lamellar microregions in the binary eutectic $\alpha\text{-Al}+\text{AlCuZnMg}$ (M) phase in the AlMg5Zn2Cu1.5 alloy, and (b) brick-like particles in the quaternary eutectic $\alpha\text{-Al}+\text{Al}_2\text{Cu}+\text{Al}_8\text{FeMg}_3\text{Si}_6+\text{Si}$ in the AlSi6Cu3 alloy, etch.1%HF, LM

In the polyphase interdendritic eutectics, some typical microregions of different morphology can be locally identified as follows:

- Binary eutectic containing multicomponent phase constituent (e.g., intermetallic phase, Fig. 6a).
- Polyphase quasi-coupled eutectic containing different phase constituents: multicomponent intermetallics, solid solutions, and pure elements (Fig. 6b).
- Polyphase microregions composed of two binary eutectics (Fig. 7a).
- Polyphase divorced eutectic containing different phase constituents: multicomponent intermetallics, solid solutions, and pure elements (Fig. 7b).

Some morphological regularities characteristic of regular or irregular eutectics are observed, for example,

lamellar (Figs. 4a,b, 6a) or chained and brick-like, according to the terminology used in Refs. [63,73] (Fig. 6b).

However, in the interdendritic microregions, polyphase divorced eutectic is a dominating morphological form. In the divorced eutectic, each of the phase constituents retains its own habit and growth mode (Figs. 5d, 7b).

PHASE SELECTION IN THE INTERDENDRITIC EUTECTICS

Processes on the Alloy Solidification Path

In the real crystallization processes of finished cooling rate, actual phase composition of alloy microstructure is controlled by kinetic factors, very often favoring those which actually are not thermodynamically privileged.

Fig. 7 Composed polyphase eutectics; (a) two microregions of the binary eutectics α -Al+Mg₂Si and α -Al+ α_c -AlFeMnSi, intermetallics in the form of Chinese script, the 6006 alloy, (b) polyphase divorced eutectic: α -Al+Al₂Cu (non-faceted, blocky)+Al₃FeMg₃Si₆ (irregular plates)+Al₇Cu₂Fe (needles)+ β -AlFeSi (needles)+Si (faceted blocks and plates), the AlSi6Cu3 alloy, etch.1%HF, LM

Fig. 8 Phase composition of the interdendritic eutectic determined by solidification conditions, solidification path simulated numerically for two models: Scheil's and Lever rule, AlSi0.9Fe0.3 alloy (β -AlFeSi, α - α_H -AlFeSi, γ - γ -AlFeSi)^[79]

Thus, the diversity of the microstructural effects observed in the interdendritic microregions results from nonequilibrium effects on the solidification path and competition between stable and metastable phases in the stage of either nucleation or growth. Models of the nonequilibrium microsegregation presented by Brody, Bower, Flemings, and Kurz and Clyne can be reduced to the simpler Scheil model.^[78–83] However, at the technological cooling rate, the concentration profile differs from the results of the Scheil model even in a quite simple system (Fig. 8).

The direct application of the theoretical models for the numerical simulation of the solidification path of the multicomponent alloys is difficult because of lack of necessary material data. Therefore, the phase image of the alloy microstructure formed in the real conditions usually does not match to that provided on the basis of the equilibrium

phase diagram and varies according to the used database and system of numerical simulation (Fig. 9).

The microstructure evolution course is determined by specific properties of the alloy components: its diffusivity in both solid and liquid phases and the interactions at S/L interfaces. Moreover, the local features of microstructure constituents, such as their morphology, size, and relative distribution, are kinetically determined by external conditions such as cooling rate, temperature gradient, and concentration field.

Local Competition of Nucleation and Growth between Solidifying Phases

Diversity of the microstructure observed in the polyphase eutectics in the final microstructure formed in the technological processes is usually explained as resulted from the local competition between solid phases stable and metastable formation. At large undercooling, the competition of nucleation dominates, whereas at low cooling rate, the competition of growth rate dominates.^[80–89]

The phase selection in the interdendritic eutectic is a well-known problem in the aluminum alloys. A special attention is paid to the intermetallic phases containing transition metals Fe, Mn, and Si. These elements, mainly Fe, are present in almost all Al alloys, often as non-intentional additions, and are very difficult to remove. The intermetallic phases bearing these elements increase the risk of defects formation, porosity, and cracks. Thus, the possible results of the selection of stable or metastable phases in interdendritic eutectics are of a special importance for the material macroscopic properties.

The main factor determining phase selection processes in the alloy solidification path is the actual driving force evolution due to temperature and local chemical composition of the solidifying liquid (Fig. 10).

At a temperature above liquidus $T > T_L$, driving force ΔG for nucleation of all solid phases is negative. As the temperature decreases, driving force becomes gradually

Fig. 9 Numerical simulation of equilibrium phase composition; alloy C319, ThermoTech (a); alloy C319, CompuTherm (b); alloy 6022, ThermoTech (c); and alloy 6022, CompuTherm (d)^[82]

Fig. 10 Competition results among different condensed phases in the interdendritic eutectic in AlFeSi alloys; thermodynamic criterion: solidification driving force ΔG vs temperature^[81] (a), and kinetic criterion: growth temperature vs growth rate (b) (β - β -AlFeSi, α_H - α_H -AlFeSi, α_C - α_C AlFeSi)

positive for subsequent solid phases. However, the value of driving force ΔG is established strictly only for stoichiometric compounds of stable chemical composition, while for solid solutions, it can have different values. Therefore, at established undercooling, the value of the driving force ΔG necessary for start of crystallization, i.e., $\Delta G > 0$, can be simultaneously achieved for different solid phases.^[81]

Phase Selection Determined by Chemical Composition of the Solidifying Liquid

The difference between the components concentrations of liquid and solid phases at S/L interface is considered as an important factor that determines the competition results among AlFeMnSi intermetallics in the interdendritic eutectics. Especially, when pre-eutectic crystallization of phase

Fig. 11 Parameter of dissimilarity Ω as affected by temperature ($^{\circ}\text{C}$); alloy AlSi0.3Fe0.2 ,^[81] (β - AlFeSi , α_1 - AlFeSi , $x_{\text{Si}} = 0.05$, α_2 - AlFeSi , $x_{\text{Si}} = 0.15$, Al_{13} - Al_3Fe)

constituent takes place, such as the α -Al solid solution or the AlFeMnSi intermetallics, some nonequilibrium changes in the chemical composition of the solidifying liquid may occur.^[78–96]

The local deviations from the equilibrium composition of the residual liquid may be caused by several factors:^[78–81,83–86,93–96]

- Difference in the Fe, Mn, and Si solubility limit in the α -Al solid solution ($C_{\text{Mn}} > C_{\text{Si}} > C_{\text{Fe}}$).
- Different diffusivity of element in liquid (this of Mn is faster than that of Fe and Si).
- Different back diffusion effects ($\alpha^{\text{Si}} > \alpha^{\text{Fe}} > \alpha^{\text{Mn}}$).
- Dependence of the Si partition coefficient on alloy composition ($k_{\text{Si}} = 0.01 + 0.002(\%\text{Si})$; $k_{\text{Si}}(\text{in AlSi } 6) < k_{\text{Si}}(\text{in AlSi } 11)$).
- Decrease of Mn solubility limit in α -Al solid solution containing Fe.

Formation of the ordered atoms distribution in such a long range as is present in the AlFeMnSi intermetallics demands diffusional displacement of atoms on a longer distance than that is necessary for non-ordered solid solutions. Thus, the preference for particular phase formation in subsequent stages of the eutectic solidification can be estimated by the value of the parameter of dissimilarity, marked as Ω , which represents the local concentration match between liquid and solid phases.^[81] The Ω value is subject to changes depending on the temperature of the solidifying liquid (Fig. 11).

The actual value of dissimilarity Ω depends on partition coefficient $k_o = C_s/C_L$ of the alloy components and their diffusivity in both phases, especially in the liquid. Therefore, the kinetic preference for phase constituents may appear independent of those expected previously by initial alloy chemical composition. The local changes of the liquid alloy composition can be characterized also

Table 6 Chemical coefficients specific for the intermetallic phases in AlFeMnSi alloys^[12,90]

Phase	(Fe+Mn)/Si		Al/(Fe+Mn)		Al/Si	
	wt%	at.%	wt%	at.%	wt%	at.%
α_c - AlFeMnSi	3–4	1.5–3	1.8	4–5	6–8	7.5–12
α_H - AlFeSi	3–4.0	2	1.9	3.5–4	6–8	7–8
β - AlFeSi	2.0	1	2.4	4.5–5	4.0	4.5–5
γ - AlFeSi	2.0	1	1.195	3	2.7	3
δ - AlFeSi	1.0	0.5	2.0	3–4	2.0	1.5–2

by chemical coefficients (Fe+Mn)/Si, Al/(Fe+Mn), Al/Si, specific for the eutectic phase constituents, actually established through solidification course (Table 6).

The values of these coefficients determined for each stage of the eutectic solidification allow to estimate the results of the competition between AlFeMnSi intermetallics: β - $\text{AlFeSi} \leftrightarrow \alpha_H$ - $\text{AlFeSi} \rightarrow \alpha_c$ - AlFeSi . For example, a local change in Fe/Mn ratio that occurs in the interdendritic liquid determines the results of selection between α_c - AlFeMnSi , α_H - AlFeSi (stable), and α_c - AlFeSi (metastable) phases. Increase in the Mn content stabilizes cubic α_c - AlFeMnSi phase and moves the concentration limit of the α_H - AlFeSi stability.^[12,13,90,91]

Phase Selection Determined by Cooling Rate

The impact of the cooling rate on actual preference for nucleation (i.e., critical nucleus radius) and growth (i.e., mechanism of atoms attachment at S/L interface) of the particular phase is very strong.^[78–98] With an increase in the cooling rate, composed sequences of the intermetallic phases were revealed:

- Al-Fe system: Al_6Fe (metastable)- Al_xFe ($x = 5\text{--}5.8$)- Al_mFe ($m = 4\text{--}4.2$)- Al_9Fe_2 - Al_qFe ($q = 4$)- Al_3Fe (stable).
- Al-Fe-Si system: α_c - AlFeSi (metastable)- α_H - AlFeSi (stable).

Most of the potential substrates for heterogeneous nucleation of solid phase are consumed by α -Al solid solution dendrites. Then, they act as the substrates for the nucleation of the equilibrium $\text{Al}_{13}\text{Fe}_4$ (Al_3Fe) phase favoring its formation at large cooling rate, although the metastable Al_6Fe phase particles are better matched to the interdendritic space.^[88] Nevertheless, the surface of the α -Al dendrites is rather not an effective substrate for most of the intermetallics nucleation. The nucleation sequence can be modified by some alloying additions such as Zr. In presence of Zr atoms, the preference for nucleation of the metastable phase Al_mFe appears. Therefore, Al_mFe phase replaces the equilibrium Al_3Fe phase.^[91]

At the stage of growth, the sequence of eutectic phases formation is determined by its mechanism and kinetics.^[94–102]

Fig. 12 Transition of stable (α -Al+ β -AlFeSi) to metastable (α -Al+ α_c -AlFeSi) eutectic in the AlFeSi alloys as induced by cooling rate increase^[95] (β -AlFeSi, α - α_c -AlFeSi)

The cooling rate (i.e., actual undercooling) was considered by Iglessis^[95] as an important kinetic factor of phase transition in the binary eutectics: (α -Al+Al₃Fe) $\rightarrow$ (α -Al+ α_c -AlFeSi), (α -Al+ β -AlFeSi) $\rightarrow$ (α -Al+ α_c -AlFeSi) (Fig. 12). With an increase in the cooling rate, two equilibrium phases Al₃Fe and β -AlFeSi were replaced by the nonequilibrium α_c -AlFeSi phase. This phenomenon was explained by difference in the S/L interface morphology. Rough S/L interface observed for particle in the shape of Chinese script, such as α_c -AlFeSi phase, privileges its growth at high undercooling, although driving force for both β -AlFeSi and α_c -AlFeSi phases might be considered comparable. The Chinese script shape reflects the tendency to match the growth front morphology to the local diffusion field in a large undercooling condition. On the front growth of the Chinese script particle, the points for the atoms attachment to the crystals

surface are more numerous than on the flat front of the faceted phase. Thus, this phase, which can change its front morphology, as α_c -AlFeSi, becomes privileged at high cooling rate.

Some results of the phase competition are determined by thermodynamic factors. The twinning of the crystal lattice observed in the crystals of the Al₃Fe phase leads to the decrease in the internal energy of the system. Additionally, due to the possibility to build in some Si atoms on twin surfaces, the field of Al₃Fe phase formation can be extended to higher Si concentration in comparison to that of equilibrium one.^[97] At large undercooling, the diffusion transport becomes more difficult; thus, conditions for growth of the faceted phases worsen. However, additions of some elements such as V or Ti (even 10–100 ppm) can lead to the extension of the lateral growth range. They can be selectively adsorbed on the growth front and therefore cause change of the growth preference for particular phase due to local decrease in the surface energy at the solidification front.^[84,97]

Application of the concept of the eutectic phase selection and precipitation sequence in the residual liquid in the aluminum alloys to control technological conditions is considered a useful tool for improving material properties. The results of experiments show that the solidification path and phase selection processes can be controlled by cooling rate change (Table 9), concentration of the alloying elements (Tables 7–10). The expected results of these procedures, important from technological point of view, are very different: change in the temperature of last eutectic crystallization (Tables 7–10), evolution of the phases sequence in the solidification path (Tables 9–10), and phase morphology change, especially needles of β -AlFeSi phase elimination (Table 9).

Examples of the results of the modification of the phase composition of the interdendritic eutectics in some commercial aluminum alloys are presented in Tables 7–10.

CONCLUSIONS

Polyphase eutectics solidifying in the interdendritic microregions in the multicomponent aluminum alloys contain several kinds of phase constituents: pure elements, substitutional solid solutions, silicides, and intermetallic phases of different ranges of chemical homogeneity and crystal structure. The main groups of the intermetallic phases present in the polyphase eutectics are electron phases, among them spd phases with transition metals and silicon (AlTM, AlTMSi) and Laves phases (MgZn_2 , MgCu_2 , MgNi_2). The phases of giant elementary cells (in Al-Mg-Zn and Al-Mg system) can be also present.

Growth mechanism of polyphase eutectics differs from that described by simple physical models based on the Jackson–Hunt rules. Nevertheless, some attempts to control the morphology of ternary eutectics during directional crystallization of AlCuAg and AlNiNb alloys were verified experimentally. However, in the technical alloys, only a small area of cooperative growth can be probably expected, mainly in the microregions of binary eutectics. The morphological regularities ascribed to the cooperative growth of three eutectic phases provided by the theoretical models were revealed in the determined process conditions in alloy microstructure images. The polyphase eutectics formed in the interdendritic liquid are mainly divorced. In these eutectics, each phase constituent nucleates and grows individually. Intermetallic phase crystal usually grows in lateral mode forming facets ascribed for specific crystallographic planes on the surface, and its eutectic precipitate retains its own particular habit.

Final phase composition of the interdendritic microregions in the technical aluminum alloys is determined by stable and metastable phases competition in the stage of nucleation and growth as affected by local cooling rate and liquid alloy composition. Phase selection occurs in the alloy solidification path depending on the effect of components microsegregation and local match of composition of the residual liquid to composition of the particular phase constituent. Some effects of the phase competition are determined by thermodynamic factors influencing the driving force of particular phase due to local changes in internal energy of the system. The surface energy at S/L interface is also an important factor that changes both nucleation and growth preferences for phase constituents depending on their morphology and crystal structure order.

Control of the phase selection effects during technological processes allows the modification of microstructure of polyphase eutectics in the interdendritic microregions. Formation of phase constituents of morphology harmful for alloy mechanical properties (e.g., β -AlFeSi phase needles) can be avoided due to inducing kinetic or thermodynamic preference for their less harmful competitors or eliminated due to change in their morphology (e.g., β -AlFeSi needles $\rightarrow$ α -AlFeSi Chinese script).

Porosity Development and Modification in Al-Si Alloys: Effect of P and Sr

J. Campbell

Department of Metallurgy and Materials, University of Birmingham, Edgbaston, United Kingdom

Murat Tiryakioğlu

Department of Engineering, Robert Morris University, Moon Township, Pennsylvania, United States

Abstract

The benefits of Sr additions to Al–Si alloys to modify the eutectic are often impaired by the development of porosity, sometimes to the degree that benefits are negated. Experimental reports are reviewed in this paper, suggesting an explanation in terms of the oxide population in the melt. The unmodified silicon particles are nucleated by AIP, which has in turn nucleated on oxide bifilms. The oxide bifilms, which are essentially cracks, are straightened by the crystalline growth of Si particles, leading to increased crack size and consequently reduced mechanical properties. The addition of Sr improves properties by suppressing the formation of Si on bifilms and thereby preventing the straightening of the pre-existing cracks. Si is now forced to precipitate at a lower temperature as a coral-like eutectic. Unfortunately, the bifilms are now freed (the primary Si particles no longer exist to grow around and sequester the bifilms), remaining in suspension in the liquid metal, allowing them to act to block interdendritic flow and aid the initiation of the formation of pores, countering the benefits of the improved structure.

Keywords: AIP; Al–Si alloys; Bifilms; Modification; Oxides; Review; Sr.

INTRODUCTION

The addition of Sr to hypoeutectic Al–Si alloys is widely practiced to refine the spacing of the eutectic phase and to thereby confer improved properties.^[1–4] The subject is reviewed by Gruzleski and Closset.^[3]

Regrettably, however, it is widely experienced that when Sr is added to Al–Si alloy to refine the eutectic silicon phase, such additions are usually accompanied by an increase in the porosity in the casting. Some users have even found that the increased porosity more than negates any beneficial refining effects, with the result that they have abandoned modification by Sr.^[5–8] Furthermore, it is salutary to note that following their review and considerable experimental investigations, Fuoco *et al.*^[9] have concluded that ‘microporosity in modified alloys has no clear explanation’.

This article draws attention to the potential contribution from bifilms, whose role so far appears to have been largely overlooked. As laid out below, bifilms seem likely to be the central factor, providing the mechanisms for

- (i) the Sr modification process
- (ii) the obstruction of interdendritic feeding
- (iii) the initiation of pores

The review summarises the current evidence for the action of Sr and proposes what the authors believe is a cogent reconciliation of all the facts.

NUCLEATION AND GROWTH MORPHOLOGY OF Si (ACTION OF P)

There is much experimental evidence^[3] to conclude that in hypereutectic Al–Si alloys, P is added in a sufficient amount to ensure that AIP precipitates in the melt in the form of compact particles. For this reason, primary Si particles grow by wrapping around the AIP nuclei to develop as compact particles.^[10]

As the P content is reduced, progressively more Si forms as coarse unmodified flakes, similar to those in hypoeutectic alloys. The reason for the different morphology may be the result of the change of morphology of the substrate. It appears that AIP continues to be the nucleating agent for Si.^[11] However, at the lower concentrations of P, it is highly likely that the phosphide particles themselves will have formed on the oxide bifilms. (The authors are not aware of any second phases forming in the liquid phase that do not nucleate and grow on bifilms. This is probably to be expected since the bifilm is perhaps the only solid available

at that stage of freezing or at least the only solid likely to be available in significant amounts.) Jorstad^[12] describes a situation in which the Si morphology can be transformed from coarse flake to particulate morphology simply by raising the P concentration.

Work by Pennors *et al.*^[13] is supportive of the hypothesis that AIP particles first nucleate on oxide bifilms and subsequently serve as nucleation sites for unmodified Si flakes. The authors present clear micro-structures in which AIP particles are seen aligning generally only along one side of a β -Fe platelet, suggestive that the AIP particles are in fact occupying one side of a bifilm and the β -Fe particle is occupying the other (Fig. 1). In addition, their observations show that the AIP particles are linearly aligned. Since the authors reason, logically, that the AIP particles nucleate first, before the β -Fe, their alignment would be difficult to explain without the prior existence of a planar (if crumpled) substrate such as a bifilm on which they precipitate and which is subsequently straightened by the growth of the Si.

Thus, in the absence of Sr, Si is likely to nucleate on the AIP and subsequently spread across its oxide substrate, explaining the often observed phosphide particle in the centres of Si particles while still requiring the bifilm to provide the generally planar substrate that the growing Si will straighten to reduce properties. Sequestering of bifilms would therefore be expected to occur in Sr-free alloys even when they contained some P.

ACTION OF Sr

On the addition of Sr to a hypoeutectic melt, both the AIP^[11] and the bifilms^[14] are deactivated as favoured substrates. Thus, neither particulate nor coarse platelike morphologies of Si can form. Thus, the melt continues to cool to lower temperatures without the formation of any Si.

Fig. 1 Phosphide particles (arrowed) aligned along β -Fe particle^[13] (courtesy of A. M. Samuel and F. H. Samuel and American Foundry Society)

We may logically assume that when the undercooling becomes sufficient, a new nucleating phase becomes favourable. This instant would be the initiation of the eutectic phase, which is known to always form at a significant undercooling.^[13] The regions of the melt experiencing the highest undercooling will be adjacent to dendrites and mould walls. Thus, the presence of a third nucleant (still unknown at this time) will trigger the initiation of a coupled eutectic. This phase has its spacing limited, of course, by small scale diffusion.

As one of the authors has proposed recently,^[15,16] the growth of the eutectic has to occur by the repeated twinning of the Si to reorient its growth to avoid collisions with neighbouring Si. Continuous abrupt changes of direction arise because of the restricted growth direction options for Si, with its characteristic faceted growth morphology, hence developing a characteristic continuous coral morphology of the Si. The high twin defect density contrasts with the near perfection of crystal structure of unmodified Si particles that grow freely, suffering minimal constraint, in the liquid. It follows that, contrary to much speculation, the high defect density of the eutectic Si is not the cause of the modification mechanism but a natural consequence.

Thus, the Sr produces benefits by

- (i) non-straightening of the population of bifilm cracks
- (ii) the fine coupled eutectic structure

Both contribute to the sought-after increase in mechanical properties, especially ductility. Although it may be argued that it remains unclear whether the main effect is the benefit from the non-straightening of bifilms or the refined eutectic structure, Cho and Loper^[17] demonstrate with Bi additions how properties are unaffected by the modification of the structure. Thus, it is most probable that the major benefit results from the non-straightening of bifilms.

Naturally, the effectiveness of the action of Sr depends on how much is added. Foundry experience indicates that poor quality metal containing much oxide requires 300–500 ppm Sr to see a satisfactory modification response. This contrasts with high metal quality for which only 50 ppm Sr is required to achieve a good level of modification. Thus, the action is in line with expectations if the bifilm hypothesis is correct. We can assume that the action of Sr is something like absorption of Sr atoms on the surface or merely at growth sites. Thus, larger areas of oxides would require correspondingly larger additions of Sr. At some addition level, it would be expected that saturation would occur, whereby additional Sr would have no additional effect.

PROBLEM OF IMPERMEABILITY OF DENDRITE MESH

It is widely, and naturally, assumed that the pasty zone in solidifying alloys is permeable to the interdendritic liquid.

That this is true in at least some alloys is supported by the evidence of the flow of interdendritic liquid in solidifying steels and high temperature Ni based alloys, in which macrosegregation is widely observed in the form of various kinds of channel defects.^[18] Larger cross-section strands and slabs of semicontinuously cast Al alloys also display a certain amount of macrosegregation, indicative of interdendritic flow. Direct measurements of permeability of the pasty zone have been reported in cast samples of laboratory Al alloys that would be expected to be relatively pure.^[19]

The results of experiments by Fuoco and colleagues^[9,20,21] over the past decade or so are therefore all the more surprising. They show convincingly, particularly when Sr is added to Al-Si alloy for the manufacture of shaped castings, that there is no mobility of the interdendritic liquid. This astonishing fact has been widely overlooked, as is clear from the continuing, if not increasing, numbers of theoretical papers assuming the unimpeded flow of liquid in the dendrite mesh of solidifying shaped castings of Al alloys.

The results of the study by Fuoco *et al.*^[9,20,21] are summarised in Fig. 2. They cast an Al-7Si-0.4Mg alloy into a sand mould whose far end is closed by a steel slide gate. The details of melt preparation were not disclosed by the authors. The mobility of the constituents of the solidifying alloy is studied by removing the slide gate at various solid fractions. At an early stage of freezing, the dendrites can move as a slurry, a stage widely known as mass feeding as is nicely confirmed in Fig. 2a. Later, when eutectic freezing starts, the dendrites are fully solidified and fixed. At this stage, the alloy is close to 45% liquid so that significant mobility of the eutectic is to be expected, but only limited eutectic liquid is seen to exude from the relatively rigid dendrite mesh in Fig. 2b. However, after adding Na, or more especially Sr, no mobility of residual liquid is observed even at the high level of 45% liquid (Fig. 2c).

This highly surprising fact is contrary to all assumptions made by those modelling the flow of liquid in the pasty zone and does not appear to be explicable by conventional physical metallurgy.

Fig. 2 Summary of modification effects by Na and Sr on mobility of interdendritic flow of Al-Si alloys showing how some liquid exudes through dendrite mesh in absence of Sr (after Fuoco *et al.*^[11])

It has been claimed by Prakash *et al.*^[22] that Sr affects the atomic ordering of the liquid structure and that this might lead to a change in viscosity and therefore explain the results in the study of Fuoco *et al.* However, this can be discounted on the grounds that changes in atomic structure of the liquid are expected to make only insignificant changes to viscosity in this alloy. In fact, significant changes to viscosity are only expected from significant concentrations of solid particles in suspension as noted in semisolid casting.^[23] Even larger changes are expected if the suspended solid has a large surface area, such as when in the form of films.

Models involving surface tension have also been proposed to explain the porosity associated with Sr addition, since the action of Sr is to reduce surface tension,^[3] as has been subsequently confirmed,^[24] thus claiming to facilitate the nucleation of pores. This hypothesis, while superficially attractive, is not likely to be accurate if pore formation, as assumed in this review, is the result of the opening of bifilms. In this case, the liquid surface is not involved; the initiation of the pore (not nucleation of course) occurs by the gradual and progressive separation of two solid (if flimsy) macroscopic surfaces. In any case, it is easily shown that nucleation of pores in a liquid is otherwise not possible: homogeneous nucleation involves huge unattainable stresses, but even heterogeneous nucleation is only a factor of 20 or so less difficult, which remains unattainable in most solidification conditions. It seems that initiation of volume defects such as pores and cracks during solidification can only occur at externally entrained features such as pre-existing pores and unbonded interfaces such as bifilms.^[25]

HYPOTHESIS FOR IMPERMEABILITY

The impermeability of the dendrite mesh is probably to be expected if there is a population of bifilms suspended in the solidifying liquid. Bifilms, as folded-in oxides, are usually extremely thin (a thickness generally measured in nanometres or micrometres) so that their presence is not generally evident.^[26] Their extreme thinness means that they have little rigidity as films. However, in a mesh of dendrites, the close periodic support of the films by the dendrite arms would assist to ensure that the dendrites are strongly bridged and thus serve effectively as dams to interdendritic flow. An additional factor is the rather thicker oxide on Sr-containing melts as a result of its greater reactivity with the environment, which would be expected to make the films more rigid. Dennis *et al.*^[27] found that although the addition of Sr to A356 alloy reduced the final thickness of the oxide considerably, there was a short term increase in the rate of oxidation that would, of course, have been important during the milliseconds in which turbulence is important in entraining surface films.

On a macroscale, an Alcoa patent^[28] describes how Sr is added to some wrought Al alloys to improve the surface finish of DC cast ingots. If surface tension was involved, the reduction of surface tension by Sr would allow penetration of finer discontinuities of the mould, thus worsening the surface finish. However, of course, the liquid does not contact the mould, being isolated from contact with its environment by its surface oxide film. The effect of a strong surface film in bridging asperities and improving surface finish has been demonstrated in a number of other alloy systems, including the employment of an alumina film on zinc alloys during the coating of steel,^[29] a graphite film on grey iron castings^[30] and a magnesia rich film on ductile iron alloys during welding.^[31]

On a microscale, the strong bridging by an oxide film can be directly and easily observed in any foundry or laboratory. When an alloy casting solidifies, a close inspection by the unaided eye of the liquid surface in the feeder (riser) top clearly reveals the residual pools of liquid descending into the dendrite mesh to feed internal shrinkage. The change in volume on freezing will be expected to occur steadily as a result of the smooth diffusion of heat from the melt. However, the descent of the liquid is not steady but occurs in sudden jumps (Fig. 3). This is seen to occur because of the sudden rupture of the oxide film on the surface of the feeder, being stretched elastically between dendrite arms.^[32] The film repairs practically instantaneously, and the process is repeated, successively storing and releasing elastic energy, until the liquid finally disappears into the mesh. The elastic energy built up before each burst of the film indicates

- (i) the strength of the film (in this case, only a single film thickness)
- (ii) its ability to prevent flow even for rather widely spaced primary dendrite arrays near the liquid surface

Fig. 3 Successive jumps of top liquid surface of feeder (riser) are denoted by series of arrows; eventually, remaining liquid may be sucked into dendrite mesh to initiate surface linked shrinkage porosity as shown

Deeper in the mesh, where the dendrites will be spaced approximately an order of magnitude closer, as indicated by the average spacing of the secondary arms (the secondary DAS), the ability of a single thickness of film to hinder flow between such close supports will be expected to be enhanced significantly. Additional ability for oxide film to effectively block flow arises because the films are often observed to be randomly tangled and so, in places, will combine to reinforce a barrier by multiple pile-up (Fig. 4), resembling other natural occurrences such as log jams in rivers. These direct observations of solidifying alloys indicate the existence of stresses in local regions of solidifying material and the strength of the oxide as a barrier in a bridging mode.

The existence of hydrostatic stresses might be expected to be relieved by inward flow of liquid from adjacent regions. The fact that this is clearly not occurring is an indication that the residual liquid in the mesh exists in isolated pockets. It is not free to flow as assumed by normal considerations of permeability. Barriers to flow clearly exist (furthermore, these barriers are not likely to be constituted by solely by dendrites or even by eutectic grains because of the complexity of interdendritic and intergranular channels that will be expected to allow flow around such obstacles).

Research^[33,34] into the quality of liquid Al alloys confirms that after addition of Sr, the melt usually appears to exhibit significantly more entrained oxide films. Emadi *et al.*^[33] find that Sr addition causes a 356 melt to oxidise approximately three times more rapidly. This enhanced rate of oxidation is confirmed by Miresmaeidi.^[35] This is the probable explanation for the greater density and size of oxide inclusions that they report. Although it has been reported that the addition of Sr results in thinner surface films,^[36] such additional oxides would have been introduced

Fig. 4 Tangle of bifilms in residual liquid presents barrier to flow, creating positive pressure above and hydrostatic tension below: tension opens the final bifilm, its internal unbonded interface decohering under hydrostatic tension to initiate growth of porosity

partly from within the Sr alloy itself, partly from its surface (as shown clearly in Fig. 3.12 in Ref. 3) and partly from the stirring that they carried out. These circumstances are commonly associated with the addition of Sr.

Thus, the fact that Al-Si alloys do not exhibit flow of residual liquid after addition of Sr may begin to be explicable as a result of the presence of either more and/or stronger barriers to interdendritic flow.

INITIATION OF POROSITY

We can now pursue this scenario further. The presence of bifilms in a solidifying matrix, in which the interdendritic liquid cannot move, raises interesting problems with respect to the mechanism of feeding the solidification shrinkage. Since macroscopic flow is prevented, flow is constricted to occur in limited localised regions between the bifilm barriers.

If there is no mechanism for the creation of porosity, then the build-up of hydrostatic tension will cause the casting to be sucked inwards, creating surface sinks, as is often observed in castings from relatively clean melts. The porosity is effectively transferred from being internal to external. However, this is not the case for most melts to which Sr has been added.

After Sr addition and the creation of a new population of oxide bifilms, it seems inevitable that the accommodation of the volume deficit on freezing will now be met by the bifilms opening, becoming pores. The mechanism is predicted by the simple fact that the bifilm is a double film, unbonded between its two halves. Thus, the unbonded film on the side suffering the hydrostatic tension simply moves to relieve the tension, thereby opening the internal unbonded interface (Fig. 4). The film on the opposite (positive pressure) side remains in place to withstand inward flow of liquid. Consequently, a shrinkage cavity is initiated and may grow to observable size. For a barrier comprised of multiple bifilms, only the last bifilm on the downstream side of the barrier would be expected to open. The remainder would merely strengthen the barrier.

OBSERVATIONS LINKING POROSITY AND OXIDES

The proposed role of oxides is supported by a number of recent observations.

1. Sr additions were found^[37] to increase viscosity of Al-Si eutectic alloys, which can be attributed to the increased rigidity of oxides in the melt (the area of oxides is likely to be similar for similar prior melt handling procedures). Several studies^[38,39] have shown that fluidity is reduced by increasing oxide content.

2. Liu *et al.*^[40] found that Sr-containing oxide (AlSrO) was found in the vicinity of the pores in Sr-modified A356 castings. Moreover, they showed that the amount of porosity is not dependent on the actual Sr level in the alloy but on the amount of Sr oxides present in the solidified casting.
3. Iwahori *et al.*^[34] found no increase in porosity level with Sr addition if the existing oxides in the melt were removed with fluxing before the addition, and the melt was vacuum degassed after the addition. In such a melt relatively free from oxides, the need for feeding did not change with increasing Sr content, remaining the same as the unmodified melt.
4. Argo and Gruzleski^[41] describe the Tatur test in which Sr appears to convert external shrinkage into internal shrinkage. A similar observation was made by Arbenz^[42] in production castings. Argo and Gruzleski describe their melt preparation only in outline, not in sufficient detail to be certain of the cause of this change. Both melts were degassed, presumably by Ar, through a lance, thus generating significant quantities of oxides. It is generally accepted that external sinks occur when the internal condition of the melt is free from nuclei for porosity, leading to internal soundness.^[43] Because the oxides in the unmodified melt became encapsulated in primary Si, and so unable to open freely to create porosity, the result was apparent internal soundness. For the modified melt, the degassing occurred after the addition of Sr, which would have folded in new oxides. Being deactivated by the Sr from becoming initiators of Si precipitation and therefore being free from Si encapsulation, these new double oxides would have been easily inflated, forming excellent initiators for internal gas or shrinkage porosity. In addition, the oxides on the external surface of the Al-10%Sr alloy rod, and its own internal bifilm population, would have added to the total oxide bifilm population of the modified alloy, enhancing the creation of internal porosity.
5. Fuoco and colleagues^[20] observe that coarse Si flakes grow out from pores in an unmodified alloy. Pores will be oxidised because they will be expected to have originated as localised features of a more extended bifilm network.^[26]
6. The improvement in tensile strength and elongation reported in the literature^[1-4] despite the increase in porosity may be explained as follows: if there are few coarse but large bifilms in the casting, such as from the ingot or other charge materials to the melt, these bifilms unfurl under the negative pressure during solidification and subsequently form the largest defects controlling properties, such as elongation. When Sr is added, additional bifilms, although smaller in size, act to decrease the effective negative pressure during solidification by their unfurling; thus, the coarse bifilms open less, resulting in smaller

largest defects. Therefore, elongation is improved, although slightly.

7. The fact that steels and, to some extent, Ni-based alloys enjoy a higher degree of permeability of their pasty zones as noted above is almost certainly the consequence of them being significantly lower in bifilm content compared to most Al alloys used in manufacturing shaped castings. This arises as a result of the greater difference in density of oxides in the denser liquid alloys. Additionally, oxides in denser liquid alloys are often partially, if not completely, liquid at the higher temperatures involved, thus encouraging the irreversible compaction of these entrained films into crumpled sticky agglomerates or even liquid drops and so allowing their rapid elimination from the melt by flotation.^[44] The semicontinuously cast Al alloys probably represent, in general, an intermediate case of a melt of a somewhat improved level of cleanness, thus exhibiting some limited degree of eutectic mobility.

CONTRIBUTION OF HYDROGEN

Several have cited the increased susceptibility of the melt to absorb hydrogen, as a result of the increased reaction by Sr with water vapour in the environment.^[26] There is no doubt that this is a major contributor on occasions, particularly if the surface of the melt is disturbed to disrupt the surface film as reported by Zhang *et al.*^[45] and as occurs in most industrial environments. However, there are experiments demonstrating that porosity increases even when the hydrogen level in the melt is unchanged.^[33] Additionally, Dahle *et al.*^[46,47] have reported that in Sr-modified alloys, the eutectic phase grows as an equiaxed grain form that could inhibit flow of interdendritic feed liquid, thus encouraging shrinkage porosity. It seems probable that there may be a contribution from this mechanism to enhance porosity, but the contribution may be limited because

- (i) analogous situations with dendrites growing together that threaten to block flow are seen in transparent models to slow down and stop before they meet, allowing the lower melting point interdendritic liquid to continue to flow^[48]
- (ii) pores occurring after modification are more spherical, indicating their earlier formation before significant growth of the eutectic grains as confirmed by Fuoco *et al.*^[20] by quenching experiments. Lee and Sridhar^[49] point out that the earlier nucleation and the suppressed eutectic growth temperature both act to give a longer time for pore growth, explaining increased porosity

Nevertheless, although all of the above proposals provide for the growth of pores, none provides a mechanism for their initiation.

NON-CHEMICAL MODIFICATION TECHNIQUES

It comes as a surprise to many metallurgists that modification of Al-Si alloys can occur without Na, Sr or any elemental additions.

For instance, primary metal taken directly from the electrolytic cell (carefully extracted using a properly designed and operated siphon, not simply removing a plug from the base of the furnace and allowing the melt to jet out) will retain its coupled eutectic structure up to 16%Si^[50] because conditions in the reduction process exclude air – in fact, the metal will not have seen oxygen at that early stage of its life. Interestingly, a large volume fraction of coarse primary Al dendrites remained features of these structures. Although these authors reported the transition to coarse unmodified flake Si at 17%Si, this is almost certainly the result of their additions of a 50%Si master alloy, which will have been previously melted and cast by pouring and so providing generous quantities of contaminating bifilms to limit the achievement of the experiment. If bifilms could be further excluded, there seems no reason to doubt that the fine coral eutectic form could not be preserved to significantly higher levels of Si.

Mechanical modification by electromagnetic stirring and ultrasonics are well documented.^[50,52] In the case of stirring, one would expect separation of bifilms by some centrifugal mechanism. Similarly with ultrasonics, the major action is usually the strong jet flow that is directed from the immersed face of the transducer, sometime known as the 'ultrasonic wind'.

In every case, these reports of Si modification in the absence of any chemical additions are consistent with an explanation based on the absence of oxide bifilms.

EFFECT OF Fe

Over recent years, it has been repeatedly reported^[53,54] that increasing levels of Fe in the Al-Si alloy refines the size of the Si particles. Cho and co-workers^[55] carry out a careful study of the modification process, concluding convincingly that this is a result of competition for nucleation sites. In terms of this current review, the early formation of β -Fe platelets on bifilms (perhaps nucleated on AIP particles on the bifilms, as discussed above for unmodified Si formation) will effectively consume many of the most effective bifilms, leaving only less effective bifilms (possibly without AIP particles) for the subsequent precipitation of Si. It seems that only careful experiments will clarify these outstanding details.

RECOMMENDED EXPERIMENTAL TECHNIQUE

Researchers attempting to define the mechanism of modification have been hampered because the bifilms are in

general invisible, being too thin to identify and remaining firmly closed as a result of the good feeding and low gas contents of the laboratory samples mainly used by careful and conscientious researchers. Thus, these well meaning efforts have ensured that bifilms have remained invisible and undetected, preventing the identification of their central role in metallurgical processes. Perversely therefore, to confirm these proposed mechanisms, test castings for research should be specially designed to be poorly fed, thus maximising the driving force for the opening of bifilms and allowing their presence to be recognised. Although high gas contents will also open bifilms to reveal their presence, the hydrogen content of melts is not easily controlled and can vary rapidly throughout an experiment as a result of the rapid rate of diffusion of hydrogen in Al alloys. Thus, for future research, specimens geometrically designed to be non-fed are likely to give more reproducible and informative results than those relying on high hydrogen contents.

SUMMARY

In summary of the mechanisms proposed in this paper, it is suggested that the complex observations in the field of modification of Al-Si alloys can be explained for the first time assuming the following.

1. At high concentrations of P in mainly hypereutectic alloys, the AIP forms as compact particles freely suspended in the melt, on which Si nucleates and grows in a particulate morphology.
2. At low concentrations of P in hypo- and hypereutectic alloys, the AIP nuclei themselves nucleate on oxide bifilms. The Si nucleates on the AIP but grows on the oxide substrate to develop a coarse platelike morphology.
3. In the absence of Sr, the Si phase precipitates preferentially onto oxide bifilms (probably decorated with AIP particles) suspended in the melt in their original crumpled and compact morphology. The subsequent planar growth of Si crystals straightens the bifilms, thereby creating long straight cracks in association with the primary Si particles. The long Si particles reflect the length of the straightened-out bifilms. The straightened cracks are proposed to be the primary reason for the reduced properties of unmodified alloys.
4. Sr deactivates both AIP and oxide bifilms as favoured growth substrates, discouraging both particulate and platelike primary Si in favour of a coral-like growth of eutectic Al-Si at a lower temperature, avoiding the straightening of bifilm cracks and thereby conferring a benefit on mechanical properties.
5. After Sr addition, bifilms are no longer sequestered into primary Si particles, therefore remaining in

suspension in the melt, available for blocking interdendritic and intergranular flow and providing the mechanism (by unfurling and inflating) for the initiation of porosity. The observed zero permeability of the solidifying dendrite mesh is proposed to be the result of the presence of bifilms. These will be rigidised by

- (i) the increased numbers and thickness of the oxide films because of the greater reactivity conferred by Sr
- (ii) increased thickness of dams because of pile-ups if the melt treatment has been particularly poor
- (iii) partial inflation by hydrogen gas (if any)

6. The reduced permeability of the dendrite mesh prevents long range flow of residual liquid. The resulting localised feeding of isolated microscopic volumes is now accommodated by the opening of the most adjacent bifilm in the surrounding bifilm dams. Thus, porosity now grows as a result of local shrinkage within the locally isolated region. This pore growth may be aided by hydrogen precipitation (if any).
7. Increased hydrogen from increased reactivity of the melt with its environment may occur if the melt surface is disturbed. Naturally, hydrogen will assist to increase porosity if there are initiation sites on which the hydrogen can precipitate. Hydrogen precipitating in the centre of bifilms will unfurl and expand them to create early, rounded pores as is commonly observed. The early formation of pores and the depressed eutectic growth temperature will provide extended time for growth, enhancing porosity somewhat. Such inflation will also tend to rigidise the bifilms, contributing further to conditions for obstruction of interdendritic feeding and to pore formation. In contrast, of course, a dry or inert environment of the melt or an undisturbed surface will reduce or avoid any contribution from hydrogen.

CONCLUSION

The action of Sr is complex. Whether Sr addition will result in increased tendency for porosity will depend on the melt preparation and quality before pouring and the amount of turbulence during the filling of the mould.^[56] These factors contribute to the oxide bifilm content of the solidifying metal, which, together with any contribution of hydrogen from the environment, determine whether the effect of Sr addition will be detrimental by increasing the number and size of pores or beneficial by avoiding the extending of bifilm cracks and producing a finer microstructure. Research to confirm these proposed explanations will benefit from the development of new, unfed, test castings.

Porosity in Aluminum Alloy Castings

Lenka Kuchariková, Eva Tillová, Juraj Belan, and Milan Uhrčík

Department of Materials Engineering, University of Žilina, Univerzitná 8215/1, Žilina, 10026, Slovakia

Abstract

The inclusions and impurities (such as oxides, carbide, defect, and so on) are formed mostly during the casting process. These inclusions and impurities reduce material properties because an increase in porosity has a tendency to form failure and corrosion of aluminum alloys. The effect of porosity on the fatigue life of AlSi9Cu3 cast alloy was studied, examining the effect of porosity size, distribution, and morphology on the fatigue behavior changes, using image analysis software. A comparison of the fatigue properties was made between material casted into a metallic mold and the material casted into a sand mold under the same conditions of gravity die casting. The fatigue properties were studied on equipment Vibrophores Amsler 50–250 HFP 5100 for material casted into a metallic mold and on Rotoflex for materials casted into a sand molds. The results show that porosity has the greatest detrimental effect on fatigue life. It was found that fatigue life decreases with increasing size of the pores surface. The experimental material casted into the metallic mold had about 98.78% smaller porosity size in comparison to the material casted into the sand mold; therefore, it showed better fatigue and mechanical properties.

INTRODUCTION

Aluminum castings have played an integral role in the growth of the aluminum industry since its inception in the late 19th century. Nowadays, aluminum is used in the production of about 50.5% of sheet, plate, and foil; 27.2% of ingots; 15.5% of extrusions and tubes; and 6.8% of other products.^[1] The transportation industry still belongs to the largest consumer of aluminum alloys, and the increasing automotive industry (car manufacturing) has led to studying the properties of aluminum alloys that are used in the manufacture of numerous car components (Fig. 1). It is very important for these alloys to have the required properties—in particular aluminum materials, from which castings are made.

Castings are produced in hundreds of compositions by all commercial casting processes, including green sand, dry sand, composite mold, plaster mold, investment casting, permanent mold, counter-gravity low-pressure casting, and pressure die casting. Aluminum cast alloys can be divided into two groups: those most suitable for gravity casting by any process and those used in pressure die casting. Melting and casting lead to the formation of disturbing textures, such as casting defects and disturbances arisen by heat treatment. Lower cooling rate setting when casting into a sand mold (sand casting) results in a granular structure and lower values of material properties.

Higher cooling rate setting when casting into a metallic mold (chill casting) results in a fine-grained structure and higher values of material properties. Reduced mechanical properties and reliability of aluminum cast alloys can be principally caused by the presence of defects and inhomogeneities, which could be preferential fatigue crack initiation sites.^[2,4–7]

The most widely used aluminum-based casting alloys are alloys of the Al-Si group. These alloys are used in various fields of application because of their excellent castability, fluidity, low specific density, and high resistance to wear, low shrinkage, very low possibilities of making cracks, and good mechanical and physical properties. In the family of cast Al-Si alloys, the Al-Si-Cu-Mg grades are frequently used in the automotive and aerospace industries. These alloys are the most versatile materials, comprising 85%–90% of the total aluminum cast parts produced by the automotive industry due to their highest strength-to-weight ratio, good thermal conductivity, excellent fluidity, hot tear resistance, and feeding characteristics that allow casting intricate shapes such as engine blocks and cylinder head sore chassis components.^[8–12] Therefore, the final properties of particular interest are strength, toughness, fatigue crack growth rate, and exfoliation and stress corrosion resistance. Each of these properties affect the microstructure features that depend on the composition, melt treatment conditions, solidification rate, casting process

Fig. 1 The use of aluminum alloys in the automotive industry (2,3): (a) Alcoa products and (b) Nemak products

and applied heat treatment. The basic microstructure features which affect the properties of aluminum casts are as follows:^[13–23]

- Matrix— α phase: dendrite cell size and dendrite arm spacing.
- Si particles: its morphology, size, and distribution.
- Second phases—intermetallic phases: its morphology (shape), size, and distribution:
 - a. Coarse insoluble particles formed during casting; soluble phases formed during casting or subsequent processing.
 - b. Smaller intermediate particles formed during homogenization.
 - c. Aging precipitates.
- Defects:
 - a. Defects arising from the metallurgical processes (cavity and internal cracks).
 - b. Defects arising during casting (porosity, cracks, and gas cavity).
 - c. Defects arising during forming (discontinuity and cracks).
 - d. Defects arising during welding (welding slag, non-trough root weld, porosity, and incomplete connection of the weld metal with the base metal).
 - e. Defects arising during heat or chemical heat treatment (surface cracks and fissures).
 - f. Defects arising as a result of fatigue attack (fatigue cracks).
 - g. Defects arising as a result of corrosive attack, thinning cross section, and so on.

The matrix, Si particles, and second phases are microstructural features visible in the microstructure. It is well known how these particles affect the properties. Also is well known how to affect the size and morphology of microstructural features in order to improve the properties of aluminum castings.^[15–20] Aluminum castings contain a lot of solidification defects (formed during the casting and metallurgical processes), but their microstructure can feature other types of defects as well, such as inclusions of slag or foundry sand. Defects often result

in poor mechanical properties including limited strength and ductility, varying fracture toughness, irregular crack initiation, and crack propagation characteristics, potentially accompanied by a lack of pressure stress. Out of aforementioned defects, solidification defects are more significant in aluminum cast alloys. Solidifications defects can be divided into three main categories:^[4–5,10,26–29]

- Gas porosity = hydrogen porosity—evolution of hydrogen gas bubbles due to a sudden decrease in hydrogen solubility during solidification; (it is the entrapment of gas—mainly hydrogen—resulting from a decrease in gas solubility in the solid metal compared to the liquid one) (Fig. 2a).
- Shrinkage porosity—shrinkage, coupled with a lack of interdendritic feeding during mushy zone solidification, resulting from the volume contraction accompanying solidification, as well as inadequate liquid metal mobility (bad feeding) (Fig. 2b).
- Hot tearing and cracks—represents the formation of an irreversible failure (crack) in the still semisolid casting. Although in most studies, hot tearing is considered as a phenomenon linked to the inadequate compensation of solidification shrinkage by melt flow in the presence of thermal stresses, there are many more factors that could be involved in the formation of cracks at supersolidous temperatures. Industrial and fundamental studies show that hot tearing occurs in the late stages of solidification when the volume fraction of solid is from 85% to 95%, and the solid phase is organized in a continuous network of grains. It is also known that a fine grain structure and controlled casting conditions (without large temperature and stress gradients) help avoid hot cracking (Fig. 2c).
- Solidifications defects, especially porosity may be classified as hidden microstructural features that endanger the safety of operation; weaken the cross section; cause notch effects; reduce resistance to corrosion; and cause leaking of products, seeds of fractures and cracks, and so on. Porosity occurs in cast Al-Si alloys during solidification due to the negative pressure generated by solidification contraction and the pressure development by evolution of dissolved hydrogen from the growing

Fig. 2 Examples of porosity in Al alloys:^[30–32] (a) gas porosity in AlSi10Mg alloy; (b) shrinkage porosity in aluminum alloy A356; and (c) an extreme example of die casting that cracked along the Fe platlets

solid into the adjacent liquid.^[33,34] Porosity can be also classified as a leading cause of reducing mechanical properties, particularly fatigue resistance, as well as a loss of pressure, stress, and degradation of the surface appearance in cast parts.^[12,25]

Gas pores are generally of round shape (Fig. 2a), isolated, and well distributed.^[10,26,35–44] There are numerous sources of hydrogen in aluminum that are prone to the gas porosity formation. Moisture in the atmosphere dissociates at the molten metal surface, offering a concentration of atomic hydrogen capable of diffusing into the melt. Other sources of hydrogen contamination can include incompletely dried refractories, remelted ingots, master alloys, metallurgical metals, and other charge components such as fluxes, tools, flux tubes, and ladles. Dissolved hydrogen levels can be reduced by a number of methods, the most important of which is fluxing with dry, chemically pure nitrogen, argon, chlorine, and freon. Alloy systems that have low solubility also have low hydrogen concentration threshold values of porosity formation and thus form porosity more easily. The hydrogen concentration at which pores begin to nucleate depends on the cooling rate rather than on the initial hydrogen content in the melt. The cooling rate has also a strong influence on the pore size and the volume of pores. Higher amounts of hydrogen may be tolerated at higher cooling rates, because of a smaller dendrite arm spacing that makes pore formation more difficult. In addition, supersaturated hydrogen in the solid can diffuse into the existing pores, causing the pores to grow or new pores to form especially during heat treatment.^[39] The second cause of porosity is dissolved gases. In this case, pores are formed because gases are far less soluble in solid metals than in liquid metals (approximately one-tenth in the case of aluminum alloys). Therefore, as a metal cools and solidify, the concentration of dissolved gases in the liquid phase increases until bubbles of gas are formed. This type of porosity is known as “gas porosity”.^[41]

The gas porosity depends on the size, distribution, location, and morphology (Table 1), and its formation can be subdivided into these three causes:^[24]

Table 1 Characteristics of gas porosity defects^[24]

Defect	Distribution	Size
Gas precipitation from solid solution	Uniform, 1–2 mm apart, near the surface	0.05–0.5 mm
Core blows	At a uniform distance under the top of the casting surface	Typically 100 mm in diameter, 10 mm thick
Air entrainment	Above ingates, especially the first ingate. Very close to the surface.	1–5 mm

- Gas held in solution in the molten metal can be precipitated as the metal solidifies, simply as a result of the reduced solubility in freezing (Fig. 3a).
- If the mold is filled under very poor conditions, air can be entrained in the metal stream and then trapped as the metal solidifies (Fig. 3b).
- The sand binders used to make the molds and cores often break down when in contact with the molten metal and the gaseous decomposition products can force their way into the solidifying metal, leading to defects which are normally known as “blows” (Fig. 3c).

Shrinkage porosity is interconnected and has an irregular shape (Fig. 2b). It is mainly caused by the inability of the liquid metal to compensate the solidification contraction.^[10,26,35–44] The size of interdendritic shrinkage voids is directly influenced by the grain size.^[26] There are two important parameters that affect the formation of shrinkage porosity: First, the liquid/solid volume fraction at the time of final solidification, and second, the solidification temperature range of the alloy.^[35] Shrinkage porosity is subdivided into (Table 2): macroporosity (size <100 μm), intermediate types (large porosity), and microporosity (size $\geq 100 \mu\text{m}$).^[24,35] The size of individual microshrinkage pores may range in length from a few microns to a few millimeters.^[41] However, in general, the occurrence

Fig. 3 Three causes of gas porosity formation:^[24] (a) hydrogen= gas precipitation; (b) air entrainment; and (3) core blows

Table 2 Sources of shrinkage porosity^[24]

Scale	Macroporosity	Intermediate types	Microporosity
Cause	Failure of liquid feeding	Failure of interdendritic feeding	Failure of interdendritic feeding
Short ΔT_f	Smooth shrinkage pipe	Centreline shrinkage	Dispersed microshrinkage
Long ΔT_f	Shrinkage sponge	Layer porosity	Dispersed microshrinkage

of microporosity in aluminum alloys is due to the combined effects of solidification shrinkage and gas precipitation.^[44] Large-scale macroshrinkage is generally a result of an unfed hot spot and is beyond the scope of this study.

According to Chambell, the shrinkage formation is divided into five mechanisms^[45] (Fig. 4):

- Liquid feeding: Bulk motion of the molten metal.
- Mass feeding: Mass feeding is liquid displacement occurring in the absence of substantial resistance. In these cases, pressure at the solidification interface and pressure in the riser system are essentially equivalent. Pressure drop develops as obstructions to the feeding path form.
- Interdendritic feeding: The progressive development of a dendritic network and localized solidification results in increased resistance to fluid flow until the pressure at the solidification front is reduced to zero, at which time a shrinkage void will form. Interdendritic feeding takes place in the interval between mass feeding and the point at which sufficient resistance develops that

liquid flow through the solidifying dendrite network no longer occurs.

- Burst feeding: Hydrostatic tension increases in poorly fed region of the casting, and this results in a collapse of the dendritic network to supply liquid metal.
- Solid feeding: This occurs when the incipient shrinkage void is filled by the collapse of the surrounding solidified metal.
- In shrinkage porosity of intermediate types, the pores are smaller and close to each other, forming a group of pores called a “cluster,” whereas gas pores are bigger, not so close to each other, and present a more circular three-dimensional geometry (more regular in shape). It has been found that the average pore size of the shrinkage pore clusters is larger than the average size of the gas pores, thus the gas pores have a smaller “area of influence” but have always a larger pore density^[40]

Numerous studies have shown that porosity has the most critical influence on the fatigue strength of Al-Si casting alloys where it acts as a preferential site for fatigue crack initiation. Porosity reduces the time to crack initiation by creating a high stress concentration region adjacent to this microstructural defect and is thus mainly responsible for decreasing the fatigue life of these alloys.^[10] The defects that affect fatigue life to a higher extent include pores, due to shrinkage or gas, and second-phase particles such as intermetallic inclusions and precipitates.^[38] Compared to porosity, the eutectic structure and intermetallic phases play a minor role in crack initiation.^[36] In the latter case, the platelet-like β -Al₅FeSi iron intermetallic phase is known to act as an active site for pore nucleation.^[10]

Fig. 4 Schematic representation of the five feeding mechanisms of shrinkage porosity^[35]

The dynamic engineering world continues to exert enormous demands for durable and cost-effective materials.^[46] That is why it is necessary to study the use of such alloys (aluminum alloys group Al-Si) under conditions of dynamic loading in order to properly understand their fatigue behavior. Fatigue is considered to be the most common mechanism by which engineering components fail, and it accounts for at least 90% of all service failures attributed to mechanical causes.^[36,47–49] We have to consider the fact that porosity elimination of cast Al-Si parts is not realistic in the industrial context due to cost increments. Therefore, presence, severity, and acceptability of porosity in cast parts should be verified and quantified during the component and process development.^[43]

Based on the above knowledge, a study was carried out to investigate the influence of porosity on the fatigue behavior of secondary aluminum cast alloy of the Al-Si group (AlSi9Cu3) used extensively in automotive applications, which was casted into a sand mold and a metallic

mold at gravity casting. The quantitative assessment and Murakami's prediction methods were used to determine the nature of the porosity and their role in changes of the fatigue behavior of differently casted AlSi9Cu3 aluminum alloy.

EXPERIMENTAL WORK

Fatigue is a problem that can affect any part or component that moves. Automobiles on roads, aircraft wings and fuselages, ships at sea, nuclear reactors, jet engines, and land-based turbines are all subject to fatigue failures.^[50] B. Zhang et al.^[51] found that fatigue cracks initiated from porosity in the aluminum material solidified at slow cooling rates, while, as cooling rate increased, the fatigue cracks initiated from near surface eutectic microconstituents.

The process of fatigue generally consists of three stages (Fig. 5):^[52] crack initiation (Stage I), progressive ("stable") fatigue crack propagation across the component (Stage II),

Fig. 5 Three stages of the fatigue fracture mechanism^[50]

and a final sudden fracture of the remaining cross section of the component (Stage III). Stages I and II are also called the fatigue region. Fatigue fracture or failure of material under stress is significantly lower than yield stress of the material used.

Fracture occurs after continuous accumulation of damage due to repeated mechanical, thermal, or mechanical-thermal loading prior to failure. In the case of fatigue failure, there is no macroscopic deformation of the solid. The whole process occurs in a microvolume at the crack tip or at a local site on the surface during the creation of a fatigue crack nucleus.^[53]

Experimental Material

The experimental material is cast AlSi9Cu3 alloy (prepared from recycled aluminum scrap) delivered from two companies—Uneko, spol.s.r.o. (sand casting), and Confal a.s. (chill casting). The AlSi9Cu3 cast alloy has lower corrosion resistance and is suitable for high-temperature applications (dynamically exposed casts without extensive requirements on mechanical properties)—it means up to 250°C. The experimental materials were not modified or grain refined. The chemical composition of the two experimental materials was checked out using arc spark spectroscopy, and it is shown in Table 3. The chemical compositions show that these alloys have comparable amount of Cu, Mg, Si, and Fe; so the formation of microstructure features will be the same. The amount of Fe is higher for both experimental materials. Therefore is expected the effect of this element on mechanical properties, formation of porosity and fatigue behavior. It is well known that this amount leads to the formation of a Fe-rich intermetallic phases group called “beta or β -needles phase,” and these phases deteriorate the properties too because of their morphology (sharp-edged needles). The deleterious effect of Al_5FeSi can be reduced by increasing the cooling rate, superheating the molten metal, or by adding a suitable “neutralizer”, such as Mn, Co, Cr, Ni, V, Mo, and Be.^[54–57] In general, copper is added to these materials in order to increase the strength and fatigue resistance without a loss of castability, but at the expense of corrosion resistance. Iron may slightly increase the strength, but dramatically decreases the ductility, especially if above 0.7% Fe, and if not corrected by manganese, cobalt, etc. The effect of the cell size and dendritic arm spacing

on mechanical properties of alloys with Si > 8% is not very significant, but in lower-silicon alloys, in which the aluminum dendrites predominate, the effect is normal.^[26] Lu in his work^[42] reported the Otte’s research examining the effect of iron on porosity formation in AlSi9Cu3 alloy. Otte has found that the total level of porosity increased slightly with iron content and that a large region of interconnected “sponge-like” porosity formed at high iron contents.

Experimental Procedure

Macroscopy analysis of the amount and formation of porosity in experimental materials was carried out using a MOTIC SM 2–168 microscope with the MotiCam 1000 camera. Light microscopy was used to analyze the microstructure and porosity of the materials after fatigue testing. The main point was quantitative analysis of porosity in the specimens, which was carried out using a NEOPHOT 32 light microscope equipped with a computer running NIS Element 4.0 image analyser software. The pore size was detected on longitudinal and transverse sections of the fatigue specimens. The methodology for microporosity prediction using statistical method proposed by Murakami presented in this study allows statistical description of an equivalent pore size. The main purpose is to predict the porosity percentage as well as the pore morphology and size. The above method is based on evaluation of the largest defect size in the field of view. A magnification of 100 $\times$ was used to evaluate the pore size according to this method. The specimens for metallographic analysis were prepared by standard metallographic procedures (wet ground on SiC papers, DP polished with 3 μ m diamond pastes followed by Struers Op-S and etched for study under an optical microscope by standard etcher Dix-Keller and 0.5% HF).

Fatigue tests of sand chill specimens were carried out on a rotating bending fatigue machine—ROTOFLEX operating at 30 Hz, load ratio $R = -1$, and at a room temperature of 20°C $\pm$ 5°C. In this type of machine, specimens with round cross sections are subjected to a deal-weight load, while bearings ensure rotation. A given point on the circular test section surface is subjected to sinusoidal stress amplitude from tension on the top to compression on the bottom with each rotation.^[49] Fatigue tests of chill casted specimens were carried out using

Vibrophores Amsler 50–250 HFP 5100 testing machine with symmetrical push–pull load and at a room temperature of $20^{\circ}\text{C} \pm 5^{\circ}\text{C}$. The specimens for fatigue tests were extracted (lathe-turning and milling operations) from the delivered circular bars (sand casting— $\varnothing 20 \times 300\text{ mm}$; chill casting— $\varnothing 18 \times 50\text{ mm}$).

Mechanical properties were measured according to the following standards: STN EN 10002-1 and STN EN ISO 6506-1. The experimental tensile and hardness specimens for experimental procedure were made from the casting with turning and milling operations. Hardness measurement for secondary aluminum alloy was performed using a Brinell hardness tester with a load of 62.5 kp, 2.5-mm diameter ball, and a dwell time of 15 s. The evaluated Brinell hardness reflects average values of at least six separate measurements. Tensile strength was measured using ZDM 30 testing machine. The evaluated R_m and A_5 reflect average values of at least six separate measurements.

EXPERIMENTAL RESULTS

Al–Si alloys usually contain Si and sometimes Mg or Cu as the main alloying elements, together with various impurities such as Fe, Mn, Zn, or Cr. These elements go into solid solution but they also form different intermetallic phases. Formation of these phases should correspond to successive reaction during solidification (Table 4).^[58–59]

Table 4 Reactions occurring at solidification of AlSiXCuX alloys^[60]

Reactions	Temperature ($^{\circ}\text{C}$)
α -dendritic network	580–620
$\text{Liq.} \rightarrow \alpha\text{-phase} + \text{Si} + \text{AlFe}_3\text{Si}$	555–570
$\text{Liq.} \rightarrow \alpha\text{-phase} + \text{Si} + \text{Mg}_2\text{Si} + \text{Al}_8\text{FeMg}_3\text{Si}_6$	500–540
$\text{Liq.} \rightarrow \alpha\text{-phase} + \text{Si} + \text{Al}_2\text{Cu} + \text{Al}_5\text{Mg}_8\text{Si}_6\text{Cu}_2$	470–500

Microstructure and Porosity Evaluation Results

The microstructure of the two experimental materials consists of α , eutectic (it is a mechanical mixture of α phase with eutectic Si), and intermetallic phases on Cu and Fe base (Fig. 6). The α matrix crystallizes from the liquid as the primary phase in the form of dendrites and is nominally comprised of Al and Si. Experimental materials were not modified, so the eutectic Si particles are in the form of platelets on both experimental materials, which manifest in the form of needles on scratch pattern—Fig. 6ab. Eutectic Si in as-cast state of alloy casted into a sand mold manifests as larger needles (Fig. 6b—2), compared to specimens casted into a metallic mold (Fig. 6a—2), which influences the decreasing tensile strength. In both experimental AlSi9Cu3 alloys, two main types of Fe-rich intermetallic phases were observed: Al_5FeSi with a

Fig. 6 The as-cast microstructure of experimental materials, etch. Dix–Keller: 1— α phase; 2—eutectic Si particles; 3—Fe intermetallic phases in skeleton like form; 4—Cu-rich intermetallic phases, especially Al–Al₂Cu–Si: (a) metallic mold; (b) sand mold; (c) metallic mold; and (d) sand mold

monoclinic crystal structure (known as “beta- or β -phase”) and $\text{Al}_{15}(\text{Mn,Fe})_3\text{Si}_2$ (known as “alpha- or α -phase”—Fig. 6ab) with a cubic crystal structure. In Brittle Fe-rich phases, Al_5FeSi platelets were identified only in a small volume and were not longer than 500 μm . Cu is primarily present in Al-Si-Cu cast alloys in the following phases: Al_2Cu , $\text{Al-Al}_2\text{Cu-Si}$, and $\text{Al}_5\text{Mg}_8\text{Cu}_2\text{Si}_6$.^[61] In the two recycled AlSi9Cu3 alloys, two Cu-phases were analyzed: Al_2Cu and $\text{Al-Al}_2\text{Cu-Si}$ (Fig. 6a,b). Intermetallic phases are larger in alloy, which were casted into a sand mold compared to alloy than those were casted into a metallic mold (Fig. 6ab). Intermetallic phases, especially Fe-rich intermetallic phases, are effective pore nucleation sites as shown in Fig. 6cd. The Fe-rich phases can act as nucleation sites for Cu-rich intermetallic phases (Fig. 6).^[62]

In the microstructure of both experimental materials, porosity was observed, but the study confirms that the two different molds caused large changes in the size, morphology, and amount of porosity. The macroscopic study shows that specimens of the material casted into a metallic mold have almost zero porosity but experimental materials casted into a sand mold have a large amount of porosity (Fig. 7).

Further studies show that both experimental materials contain mostly solidification defects, especially shrinkage porosity (Fig. 8). The material casted into a metallic mold has the following shrinkage porosity types: mostly microporosity, but in very small volumes, macroporosity were

also identified (Fig. 8). The material casted into the sand mold mostly has shrinkage porosity types: macroporosity and microporosity in small volume (Fig. 8). This figure confirms that porosity in AlSi9Cu3 cast alloy casted into a metallic mold is very small, and porosity is greater in the material casted into a sand mold (Fig. 8).

Quantitative Analysis of Porosity Results

Quantitative analysis of shrinkage porosity confirms that the material casted into a metallic mold has a very small size of pores in comparison to the same material casted into a sand mold, because the material casted into the metallic mold has about 513 μm^2 average size of shrinkages, compared to 42 301 μm^2 in the material casted into the sand molds, which is about 98.78% larger than the average size (Fig. 9).

The analysis shows that the amount of porosity in the material casted into a metallic mold was smaller in comparison with the material casted into a sand mold (Fig. 7). The average surface fraction for the material casted into a metallic mold was 0.7% and for material casted into a sand mold was 1.7%, which is about 58.82% higher porosity. The evaluation of porosity in AlSi9Cu3 cast alloy casted into two different molds shows that the casting process is very important because the pores in the specimens casted into a sand mold are very large, and

Fig. 7 Amount of porosity in AlSi9Cu3 alloys casted into different molds: (a) chill mold (magnification: 7.5 $\times$) and (b) sand mold (magnification: 7.5 $\times$)

Fig. 8 Morphology of microshrinkage porosity in AlSi9Cu3 cat alloys casted into different molds: (a) metallic mold and (b) sand mold

Fig. 9 Quantitative analysis of microshrinkage porosity in AlSi9Cu3 alloys casted into different molds: (a) size of porosity and (b) amount of porosity (surface fraction of porosity)

this fact is important for understanding the changes in the properties of these types of aluminum alloys. It is necessary to keep in mind the effect of the matrix, Si particles, and second phases (their size, amount, and morphology) on the properties too.

These facts show that the material casted into a metallic mold would have better mechanical and fatigue properties because of the size, amount, morphology of porosity, and other structural features.

Mechanical Properties

Alloy AlSi9Cu3 casted into a sand mold has a significantly smaller value of HBW and UTS than the same alloy casted into a metallic mold (Fig. 10). The tensile strength of the material casted into sand molds was 143 MPa, and that of the material casted into metallic molds was 211 MPa (Fig. 10). The material casted into metallic molds has about 32% higher tensile strength compared to the material casted into sand molds. The Brinell hardness for the material casted into sand molds was 73, and that for the material casted into metallic molds was 98 (Fig. 10). The material casted into metallic molds has higher Brinell hardness by about 25% compared to the material casted into sand molds.

Fig. 10 Mechanical properties of the two experimental materials

Fatigue Properties

To confirm the pore size effect on the fatigue properties of experimental material, the specimens at the same amplitude level were loaded for comparative purpose.

- Specimens casted into a metallic mold:

Experiment 1—three specimens tested at the same stress amplitude of 80 MPa, one of them was not broken after 2×10^7 (the specimens that have reached these numbers of cycles without breaking are defined as run-out), the others were broken before reaching the specified number of cycles for fatigue test 2×10^7 (Table 5).

Experiment 2—two specimens tested at the same stress amplitude of 85 MPa, but both were broken before reaching the specified number of cycles for fatigue test 2×10^7 (Table 5). The difference was that one of them has reached a larger number of cycles than the other prior to failure.

- Specimens casted into a sand mold:

Experiment 3—two samples tested at the same stress amplitude of 65 MPa, but both were broken before reaching the specified number of cycles for fatigue test 2×10^7 (Table 5). The difference was that one of them had reached a larger number of cycles than the other prior to failure.

Quantitative analysis of the size and amount of porosity was completed using Murakami's method on all fatigue experimental specimens. Murakami's method was applied to the characterization of the pore size population according to the largest extreme value distribution (LEVD).^[27,43,63] The summarizing table was elaborated (Table 5), containing all measurements of quantitative assessments, Murakami's method, fatigue, and mechanical properties, to better understand the relationship between porosity and properties. The results of quantitative assessment (average area of defects) show the important effect of shrinkage casting defects on fatigue resistance of experimental materials (Table 5).

Table 5 Results for AlSi9Cu3 experimental materials casted into the two different molds

Experiment	Specimens	Ultimate tensile strength (MPa)	Stress amplitude (MPa)	Number of cycles N_f	Average area of defects (μm^2)	Estimated largest pore size (μm) for $S = 10 \text{ mm}^2$
Materials casted into metallic mold—experiment 1	A	211	80	20000086	880	39.8
	B			10185036	3689	106.11
	C			1210151	7208	196.6
Materials casted into the metallic mold—experiment 2	D	211	85	2821798	2498	98.4
	E			1522984	5959	181.4
Materials casted into the sand mold—experiment 3	F	143	68	2156500	25516	233.7
	G			1400050	37414	251.1

The first group of experimental materials casted into a metallic mold (samples A, B, and C—Table 5) included specimens tested at the same stress amplitude. These showed different results in the number of cycles prior to failure. Specimens A were the specimens marked as run-out, because these specimens reached a number of cycles over 2×10^7 . Specimens B and C were specimens that broke before reaching the 2×10^7 cycle. Table 5 shows that specimens A have the smallest pore size value of $880 \mu\text{m}^2$ and specimens C have the pore size value of $7208 \mu\text{m}^2$. The difference in the pore size was $6320 \mu\text{m}^2$, which is about 87.8% larger size when comparing these two specimens. These results show that the size of pores has a greater effect on fatigue resistance of the experimental material, because while alloy A withstands over 2×10^7 , alloy C withstand only 1.2×10^6 , which is about one order lower fatigue resistance.

The second group of experimental materials casted into the metallic mold included specimens D and E (Table 5). The specimens were tested at the same stress amplitude and showed different results in the number of cycles prior to failure, but both of them were specimens that broke before reaching the specified number of cycles 2×10^7 (Table 5). With respect to average pore size value, prior to failure, Samples D reached higher number of cycles (2821798) with $2498 \mu\text{m}^2$ than specimens E, which have reached a smaller number of cycles (1,522,984) $5959 \mu\text{m}^2$ (Table 5). These results show that the size of pores also has a greater effect on fatigue resistance of the experimental material, because while alloy D withstands over 2.8×10^6 , alloy E withstands only 1.5×10^6 . These results confirm that the pore size has a greater effect on changes in fatigue resistance of the experimental material.

The third group of experimental materials casted into the sand mold included specimens F and G (Table 5). The specimens were tested at the same stress amplitude (68 MPa) and showed different results in the number of cycles prior to failure, but both of them were specimens

that broke before reaching the specified number of cycles 2×10^7 , like the specimens used for experiment 2 (Table 5).

Samples F reached a higher number of cycles prior to failure (2156500) and had a smaller value of the average pore size ($25516 \mu\text{m}^2$) compared to specimens G that reached smaller number of cycles prior to failure (1400050) and had a larger value of the pore size ($37414 \mu\text{m}^2$) (Table 5). The difference in pore size was $11898 \mu\text{m}^2$, which is about 32% larger size, when comparing these two specimens. These results show that the pore size also has a greater effect on fatigue resistance of the experimental material, while alloy F withstands over 2.1×10^6 , alloy E withstands only 1.4×10^6 . These results confirm that the pore size has a greater effect on changes in fatigue resistance of the experimental material also in the specimens casted into a sand mold.

Based on these results of quantitative analysis of pore size and fatigue resistance, it can be said that the following is valid for the two experimental materials: properties deteriorate with increasing values of pore size (Table 5). It is very important to keep in mind the effect of other structural features; Table 5 shows that it does not depend only on porosity. For example, the specimens from experiment 1 (B) reach a higher number of cycles prior to failure (10185036) compared to the specimens from experiment 2 (D) (2821798), but specimens B have a larger value of the average pore size ($3689 \mu\text{m}^2$) compared to specimens D ($2498 \mu\text{m}^2$). Comparison of these two specimens shows that specimens B have largest pores inside the material, and smallest ones near the surface, while specimens D have largest pores near the surface of experimental specimens (Fig. 11).

However, it is important whether the pores are situated inside the material or near the surface of experimental specimens, and whether there is a higher volume of the smallest pores or larger pores in materials; the value of stress amplitude; and so on.

Fig. 11 Quantitative assessment of microshrinkage casting defects in AlSi9Cu3 cast alloy casted into a metallic mold

Differentiation between experiment 2 and experiment 3 was also made to fully compare the results. In experiment 2, two specimens were casted into a metallic mold, and they do not reach the number of cycles for fatigue test (2×10^7). The same applies to experiment 3. The difference was in the stress amplitude and the size of pores. The results show that the material casted into a sand mold have a very large value of average pore size in the order of tens of thousands (Table 5), while the material casted into a metallic mold has an average pore size in the order of thousands. These facts show the greatest influence of different molds on the microstructure of experimental materials; therefore, it is impossible that material casted into a sand mold have better properties.

The aforementioned results show that the different amount and size of shrinkage casting defects must have the greatest influence on changes in fatigue behavior; therefore the aim of this study was to predict the maximum pore size in real casts form in these types of experimental material. To predict the real pore size, Murakami's method was used. The control area of the measurements was the surface, (S_0) = 1.86 mm². For prediction of maximum pore size in real castings, the measured values were extrapolated to a cross-sectional surface (S) = 10 mm² (typical of a fatigue specimen—Table 5, Fig. 12); but, according to these experiments, there is a possibility to predict the pore size for different surfaces (e.g., 100 and 1000 mm²). All the measured and predicted results of the largest pore size are shown in Fig. 12. The area^{1/2}

represents the calculated size of the largest pores, which was measured using image analysis, and y_j is the reduced variates. These results were analyzed using Gumbel's distributions. The predicted and estimated largest pore sizes for $S = 10$ mm² for each experimental state are shown in Table 5.

The results of fatigue properties and results of measurement and prediction of pore size confirmed that the pore size has a greater influence on the fatigue behavior. The best fatigue properties were observed in the specimens that have a smaller size of pores for both experimental materials (Table 5 and Fig. 12: rhombus—experiment 1, square—experiment 2, triangle—experiment 3). The results of the fatigue tests carried out on the specimens extracted from experimental circular bars are presented in the S/N (stress amplitude vs. cycles to failure) diagram in Fig. 12d. The number of cycles that the specimens had to reach without breaking was 10^7 for the material cast into a sand mold, and 2×10^7 for the material cast into a chill mold. The specimens that reached these numbers of cycles without breaking are defined as run-out. The range of fatigue lifetime for 10^7 cycles ranged from 29 to 49 MPa—average value of fatigue lifetime for 10^7 cycles was about 39 MPa in the material casted into sand molds (Fig. 12d). The range of fatigue lifetime for 2×10^7 cycles was 50–80 MPa—average value of fatigue lifetime for 2×10^7 cycles was about 67.5 MPa in the material casted into metallic molds (Fig. 12d). The predicted value of fatigue lifetime for 10^7 cycles for the material cast into metallic molds was

Fig. 12 Comparison of the LEVD plots of equivalent pore size and fatigue properties of both experimental materials: (a) LEVD—experiment 1; (b) LEVD—experiment 2; (c) LEVD—experiment 3; and (d) fatigue properties of both experimental materials

68 MPa according to Basquin's equation obtained from the diagram (Fig. 12d). Fatigue resistance was found to be about 43% higher in push–pull test than in rotating bending test due to the different material volumes under high stress, but also due to the different casting methods that were used to produce the experimental specimens.

CONCLUSIONS

The presented study has confirmed the differences in the production of aluminum castings using different casting molds. Materials casted into a metallic mold have the smaller size of microstructural features (Si particles, inter-metallic phases, and defects) in comparison to the material casted into a sand mold.

The shrinkage porosity evolution in experimental materials shows the influence of different molds on porosity creation. The material casted into a sand mold has a greater porosity size in comparison to the material casted into a metallic mold, which is probably associated with cooling rates of these materials.

Murakami's method confirmed the presence of the largest pores in the material casted into a sand mold, and using this method, the largest pore size was predicted that can be observed in real materials.

Mechanical properties of the material casted into a sand mold were deteriorated. The material casted into a metallic mold has about 32% higher tensile strength and about 25% higher Brinell hardness, in comparison to the material casted into sand mold.

The fatigue lifetime of AlSi9Cu3 cast alloy casted into a metallic mold and a sand mold without modification or grain refinement was influenced by the presence of shrinkage casting defects in the microstructure. Against it was confirmed that the same material can withstand the stress amplitude for 2×10^7 cycles and the other material cannot. The study shows that specimens casted into a metallic mold have fatigue lifetime by about 43% longer for 10^7 cycles in push–pull test (68 MPa), compared to the material casted into a sand mold during rotating bending test (49 MPa). This was due not only to the presence of different size, morphology, and amount of shrinkage casting defects, but also other structural features.

Porosity in Aluminum Welds

M. Mazur

Department of Welding, Polytechnic of Slask

Abstract

Porosity constitutes the main defect in aluminium welds. It is generally assumed that the basic reason for its formation is the presence of hydrogen. Hydrogen can originate from a variety of sources. Major sources of hydrogen are surface contamination of both the parent and deposited metals in the form of hydroxides, hydrocarbons or oxides with adsorbed moisture. Another source of hydrogen can be impurity of the gas shield associated with either moisture or air sucked into the arc atmosphere if an incorrect welding procedure is adopted. It has been found that even 2 ppm of hydrogen in the molten metal, or 250 ppm of hydrogen in the gas shield can be sufficient to produce porosity in aluminium welds.

Keywords: Adsorbed gas; Blisters; Hydrogen; Oxygen film; Porosity; Solidification.

Porosity constitutes the main defect in aluminium welds. It is generally assumed that the basic reason for its formation is the presence of hydrogen. Hydrogen can originate from a variety of sources. Major sources of hydrogen are surface contamination of both the parent and deposited metals in the form of hydroxides, hydrocarbons or oxides with adsorbed moisture. Another source of hydrogen can be impurity of the gas shield associated with either moisture or air sucked into the arc atmosphere if an incorrect welding procedure is adopted. It has been found that even 2 ppm of hydrogen in the molten metal, or 250 ppm of hydrogen in the gas shield can be sufficient to produce porosity in aluminium welds.^[1]

A film of oxides with adsorbed moisture on the surface of the welding wires, or their contamination by hydrocarbons, as well as the hydrogen contained in the wire material, influence formation of porosity in welds to a much higher degree than the presence of the same impurities in the parent metal. This is due to the involvement, in the process of weld deposition, of a large percentage of the wire surface – as compared with the volume – and also of the filler material. It is mainly for this reason that, for instance, a higher degree of porosity is encountered in the MIG welding process than in the TIG method; thinner welding wires are employed in the former operation. Also, conditions for the solidification of the deposited metal are more favourable in the TIG process and consequently degassing of the metal can be much better. The sources of hydrogen in MIG welding of aluminium are indicated in Fig. 1.

The pronounced tendency of aluminium to form porosity is sometimes explained by the high ratio of the maximum solubility of hydrogen to its solubility at the melting

temperature (Fig. 2). For aluminium,^[2,3] this ratio has a value of 70 whereas for iron it is 1.6.

The formation of blisters can be examined from the point of view of both their generation and their further development. For a blister containing hydrogen to form, it is necessary that the pressure in the blister is in excess of that in the molten metal. For the welding conditions this relationship is represented by the following inequality

$$P_{H_2} \geq P_z + (2\sigma/r) = 1 + (2\sigma/r)$$

where P_{H_2} is the pressure of hydrogen in the blister, p_z is the gas pressure above the molten pool (equal to 1 atm), σ is the surface tension of the molten metal, and r is the radius of the blister.

It follows from the above inequality that for blisters to develop it is necessary that their nuclei, of specific radii (with $r \rightarrow 0$, $P_{H_2} \rightarrow \infty$), are present in the molten metal, and, further, that the partial pressure of hydrogen is sufficiently high. In the present case, the nuclei of blisters consist usually of microvoids situated on the uneven surface of a stable particle, mainly an oxide wetted by the molten metal (Fig. 3).

During solidification of the weld, as a result of reduced solubility, the dissolved hydrogen will diffuse into the microdiscontinuities and will change in character from atomic to molecular, thus increasing the size of the blisters.

It is felt that for porosity to be present in aluminium welds the following conditions are necessary:

- a hydrogen concentration exceeding 0.69 cm³/100 g
- the presence of microdiscontinuities that form blister nuclei^[4]

Fig. 1 The sources of hydrogen in MIG welding of aluminium and its alloys^[2]

Fig. 2 A comparison between the solubility of hydrogen in aluminium and iron^[2]

Fig. 3 The mechanism of blister formation on oxides in the areas not wetted by the molten metal

The development of blisters will depend on the following factors:

- the rate of weld solidification
- the rate of hydrogen diffusion
- the total hydrogen concentration in the molten metal^[5]

High rates of weld solidification will be advantageous from the point of view of slowing the development of blisters because of the short time in which the diffusion of hydrogen can take place. In consequence, the blisters thus formed will be small. With reduction in the rate of cooling, the time in which the development of blisters takes place increases and therefore a higher concentration of them can be expected. At very low rates of solidification, the time for the eventual evaporation of hydrogen, contained in the blisters, is long and this will favour the

formation of blisters of high concentration. A model of blister formation in aluminium has been proposed by Uda and Ohno.^[6] Investigations into the levitation melting of aluminium in a hydrogen atmosphere indicate that the main factor behind the formation of porosity is the difference between the solubility of hydrogen (H_L) at a given temperature (H_{L1}) and its solubility near the melting temperature (H_{L0}), see Fig. 4.

An increase in porosity is observed as H_{L1} is increased. For instance, when melting aluminium in a hydrogen atmosphere (100% H_2) at a temperature of 700°C no porosity was observed, but when specimens were melted at a temperature of 1100°C porosity amounted to some 30% of their volume.

In conditions of equilibrium, with hydrogen pressure of 1 atm and a temperature T_1 , gas blisters do not form in the

Fig. 4 Solubility of hydrogen in aluminium as a function of temperature

Fig. 5 A model of porosity formation in aluminum

molten metal (Fig. 5). However, if sudden cooling to a temperature T_2 takes place, then, because of the reduced solubility of hydrogen, microblisters of gas are formed; their nuclei being stable particles of non-metallic impurities, such as, for instance, aluminium oxides. As the cooling process progresses, and when the molten aluminium reaches a temperature T_3 , solidification begins along the side walls (in the case of the parent metal welds). Gas blisters present in the melt near the growing grains are being gradually pushed into the still molten part of the specimen. As a result of this, some blisters merge to form larger ones, and others may become trapped in the growing grains. For a temperature T_4 , the distribution of porosity in the specimen after solidification is as in Fig. 5. No increased concentration of porosity is observed in the central part of the weld because the electrodynamic forces, which stir the molten pool, distribute the dissolved hydrogen uniformly throughout the whole volume of the metal.

The moisture adsorbed on the surfaces of the parent and deposited metals has a very significant effect on hydrogen concentration in the molten pool. The following reaction takes place within the weld zone:

Consequently, the hydrogen dispersed in the molten metal is at a high pressure.^[7] The very significant effect of moisture on the formation of porosity is indicated by the investigations of Ref. [8] which show that addition of hydrogen to argon reduces porosity in welds to a higher degree than does the use of purposely premoistened argon.

Moisture can be introduced into the arc atmosphere in the course of welding as a result of condensation occurring in the gas welding hoses and in the welding torch, or because of using impure argon from a gas cylinder. The degree of contamination of the shielding gas by moisture can be assessed from the value of the gas dew point. According to Sieverts Law, it can be expected that a proportional increase in hydrogen concentration in the molten pool will accompany a rise in the shielding gas dew point. The investigation described in Ref. [5] showed that no blisters were formed in 3003 AlMn1Cu alloy weld when using 1100/A199.0/filler rod and an argon shield with the dew point of the gas lower than -40°C . The concentration of blisters in the welds increased with increasing dew point of argon.

It was also found that welds deposited in a helium atmosphere showed a much lower degree of porosity than those formed in argon or in a 65% He+35% Ar mixture gas shield. It is thought that this is associated with the effect of dissociation of helium on the dissociation of water and hydrogen. Argon dissociates to a much smaller degree in an electric arc than does hydrogen. Similarly, small quantities of oxygen and nitrogen, when added to argon, have the effect of reducing the degree of weld porosity. The explanation of this is the same as that in the case of helium.

According to Woods,^[9] the chemical composition of the weld also influences the formation of porosity. In the solid state, pure aluminium is characterised by a lower solubility of hydrogen, but by a high rate of hydrogen absorption. Because of this, it is highly susceptible to the formation of porosity in the weld. In some tests on TIG welded aluminium and its alloys using argon intentionally contaminated with hydrogen, porosity was found in pure aluminium when the hydrogen content in the arc was 120 ppm. However, in the AlMg1 alloy porosity was formed when the hydrogen content was 625 ppm, and in the AlMg6.5 alloy when it was 1090 ppm.

The volume of absorbed gas is also influenced by the welding parameters of the process through the medium of the change in the rate of absorption. When welding aluminium, hydrogen absorption, and therefore the formation of porosity, can be minimised by employing low welding currents, short arcs, high rates of gas flow, and high rates of welding. However, a reduction in the rate of welding, and increase in the current intensity result in a lower rate of solidification and they thus increase the period in which blister formation and their floating out of the weld can occur.

Although, in general, various AlMg alloys are less susceptible to formation of porosity, high porosity can occasionally be present. A different mechanism is envisaged here as an explanation.

The oxygen film on the surface of an alloy of this type consists of Al_2O_3 , MgO, and $\text{Al}_2\text{O}_3\cdot\text{MgO}$ spinel, and has a lower density, more structural defects, and a higher moisture content than an Al_2O_3 film on the surface of aluminium. In the course of welding, during the melting of the parent and deposited metals, some moisture present in the

metal decomposes and produces hydrogen. This hydrogen gas, bypassing the solubility phase, takes the molecular form and forms blisters.^[10] The shape of the joint and the welding position can also affect the formation of porosity. The more difficult the welding position, the higher is the volume of retained hydrogen. Particularly susceptible to formation of porosity are welds deposited in horizontal and overhead positions. It is also known that porosity can form on the weld edge; this often calls for the use of special plates.

Out of a variety of techniques used in welding of aluminium and its alloys, one particularly susceptible to porosity formation is welding with coated electrodes. This is due to the presence of hygroscopic and hydrated compounds in the material of a coated electrode.

Abstract

The production of aluminum alloys through powder metallurgy (PM) processes allows for the manufacture of net- or near-net-shape components in a cost-effective and sustainable manner. The high reactivity of aluminum metal, however, complicates PM processing, and special attention must be given to certain steps during production, particularly sintering. PM processing conditions strongly affect the structure and porosity of aluminum PM alloys, which ultimately determine their material properties and performance. In this article, the fundamental aspects of the commercial production of aluminum PM alloys are presented, along with the effects of production conditions on the structure and porosity of aluminum PM alloys. The properties and performance of aluminum PM alloys are then analyzed and interpreted with respect to their structure and porosity.

Keywords: Additive manufacturing; Aluminum; Compaction; Powder metallurgy; Secondary operations; Sintering; Structure; Porosity; Surface engineering.

INTRODUCTION

Powder metallurgy (PM) is a highly versatile manufacturing technology that can serve as a low-cost, sustainable, alternative to traditional metal processing methods as well as enable exotic chemistries and microstructures to achieve material properties unattainable through other production processes. The generic PM process involves the production of powder, its consolidation into a friable compact, and sintering of the compact at an elevated temperature to bond particles together, and may also include additional processing steps related to powder consolidation and handling or optional secondary processing steps after sintering.

Aluminum alloy materials fabricated via PM offer many of the advantages of traditional wrought and cast aluminum alloys while also providing the inherent benefits of PM manufacturing—cost-effective mass production of net- or near-net-shape components and sustainability in manufacturing through high material utilization. However, as a reactive metal, processing aluminum by PM is rife with complications and challenges and requires much more meticulous care compared to processing traditional ferrous, cuprous, or nickelous PM materials.

In this article, the fundamentals of the PM processing of aluminum alloys are presented. The scope encompasses conventional PM processing and emerging additive manufacturing technologies, with an emphasis on commercial practices. The discussion begins with a background on aluminum PM alloy systems, followed by a review of powder production, compaction, and sintering practices, and the effect of processing conditions on structure and porosity,

before finally culminating with a review of the properties and performance of aluminum PM alloys. Where applicable, comparisons are made to traditional wrought or cast aluminum alloys.

BACKGROUND

The PM Process

PM has been generally defined as the art and science of producing metal powders and of utilizing metal powders for the production of massive materials and shaped objects.^[1] The premise of using PM as a manufacturing process may be threefold: to produce precise and complex parts in an economic fashion, to produce materials with unique microstructures and properties, and to produce materials that are difficult or impossible to process by other means. For aluminum alloys, PM may be utilized for one or more of these reasons.

The conventional, or “press-and-sinter,” aluminum PM alloys primarily aim to improve production economics of complex parts and account for the majority of commercial aluminum PM alloy production. These alloys are produced by a relatively straightforward process, outlined in Fig. 1. Additively manufactured, or “3D printed,” aluminum PM alloys also serve to reduce production costs of complex parts and are playing an increasing role commercially.^[2] These alloys circumvent the powder compaction step through direct freeform fabrication from aluminum powder, as shown in Fig. 1. PM is also used to produce

Fig. 1 Flowsheet for conventional and additive manufacturing aluminum PM processes

“rapid solidification processed” and composite aluminum alloys,^[3] many of which require additional processing steps and consolidation to full density, and are beyond the scope of this article.

The majority of conventional aluminum PM alloys are composed of different powder ingredients which are mixed together to form a “premix” as shown in Fig. 1. To produce a PM part, the premix is first compacted, or “pressed,” into a compact of net or near net shape. The compact is then sintered at an elevated temperature to bond powder particles together and may be subjected to further secondary operations such as “repressing.” Aluminum PM alloys are also additively manufactured from premixes or single-component “pre-alloyed” powders, as shown in Fig. 1. In this case, a focused laser is used to locally sinter or fuse a thin layer of powder in predetermined areas; thereupon, another layer of powder is spread across the “build platform” and the process is repeated. The manufacture is “additive” in the sense that parts are built up layer by layer. In either case, the final product is a component of net shape produced with low cost due to the high productivity, efficiency, and automation of PM manufacturing.^[1]

Historical Development

The first commercial aluminum powder was manufactured in the early 1900s by milling and stamping thin aluminum sheet into flake powder, to be used primarily as an additive pigment in paint, but this contained high oxide contents and size characteristics which were inappropriate for PM.

The atomization technology and infrastructure for aluminum matured during World War II where atomized aluminum was used extensively as an incendiary.^[4] The lower oxide content and customizable particle size distribution of atomized aluminum eventually led to its use in PM after the war.

The principal technical difficulties preventing the large-scale commercialization of aluminum PM alloys were the refractory aluminum oxide layer and the severe galling and seizing characteristics of aluminum toward steel dies.^[4–6] Early investigators realized that in order to adequately sinter aluminum, the refractory oxide layer on powder particles had to be removed or disrupted by high compaction pressures or sintering in the presence of a liquid phase, but reoxidation during sintering was a major concern.^[7–9] The remaining problems with aluminum PM were eventually overcome by selecting a powder source with appropriate size and shape characteristics, using an admixed solid lubricant with a low moisture and ash content, and maintaining close control over the sintering temperature and atmosphere. The large-scale commercial production of aluminum PM alloys began in the 1960s.^[10,11]

Alloy Systems and Temper Designations

Most aluminum PM alloys are based on the alloy systems of traditional wrought or cast aluminum alloys and may be conveniently classified according to the wrought aluminum alloy system,^[12] described in Table 1. Each of these alloying elements, or combination thereof, is characterized by a solid solubility in aluminum metal that generally defines the heat treatability of the alloy. Typically, alloys containing significant amounts of copper, a combination of magnesium and silicon, or a combination of zinc and magnesium are age hardenable.

The majority of commercial aluminum PM alloys are of the heat-treatable type, the compositions of which are shown in Table 2. Since a principal benefit of the PM

process is the production of net shape components, it is logical to induce strengthening via precipitation hardening as this induces virtually no dimensional change, and heat-treatable alloys maintain ductility prior to aging which eases some secondary operations. Furthermore, as sintering is an elevated temperature process, alloys of this type experience naturally aging at room temperature after sintering, which frequently negates the need for further strengthening steps. In additive manufacturing, hot shortness is of a larger concern, and these are typically more casting-type alloys containing silicon, the premier alloy being “AlSi10Mg” (Table 2).

In general, all aluminum PM alloys contain some amount of magnesium (Table 2), which is necessary to reduce the aluminum oxide layer on particles and enable sintering. In some cases, PM alloy chemistries have surpassed those of traditional alloy systems and been engineered to elicit a superior response to sintering or additive manufacturing, particularly some proprietary compositions with trace or activating element additions. In addition to the compositions listed in Table 2, premixes may contain 1–2 wt% admixed solid lubricant, which must be burnt off prior to sintering, to facilitate compaction. Up-to-date information regarding commercial aluminum PM alloys, as well as technical standards, may be obtained from the Metal Powder Industries Federation (Princeton, NJ, USA).

The thermal and mechanical treatment and sequence history of aluminum PM alloys may be indicated by a temper designation, similar to traditional aluminum alloys but with some slight modifications to conform to standard PM practices. Some of the more common PM alloy tempers that have been adopted in the literature are shown in Table 3. The primary modifications for PM tempers are that thermomechanical treatments and sequences are described with respect to sintering or additive manufacturing, rather than hot working, and that repressing is used for the majority of cold working operations. The T1 temper simply involves cooling from the sintering temperature

and represents the lowest cost temper for aluminum PM alloys. The T2 temper involves a repressing operation after sintering and is the most common temper for conventional aluminum PM parts;^[12] this generally allows for manufacture close to net shape by using repressing to improve dimensional tolerances after sintering. In additively manufactured aluminum PM alloys, a stress-relieving partial anneal is sometimes used to produce intermediate properties.

Applications

A key advantage of PM manufacturing is its net-shape production capabilities, and, accordingly, aluminum PM has been utilized for the production of small, complex parts in place of more expensive die cast and machined aluminum alloys. Generally, aluminum PM parts retain the attractive

Table 3 Some temper designations used for aluminum PM alloys

Temper	Description
O	Annealed 1 h, furnace cooled in nitrogen at a maximum rate of 10°C h ⁻¹ to 260°C or lower
T1	Cooled in nitrogen from sintering temperature to 260°C or lower at uncontrolled rate, air cooled to room temperature
T2	As sintered, repressed
T4	Solution heat treated in air, cold water quenched, naturally aged
T41	Repressed, heat treated to T4
T6	Solution heat treated in air, cold water quenched, artificially aged
T61	Repressed, heat treated to T6
T8	Solution heat treated in air, repressed, artificially aged

Note: Heat treatment regimen and temperature are specific to alloy composition.

properties of aluminum—specifically, its light weight, natural corrosion resistance, and high thermal conductivity. Conventional and additively manufactured aluminum PM alloys may be better suited toward different applications, and the choice of production method should be specific to the end use and production requirements.

Good candidate parts to produce via conventional aluminum PM are relatively small, complex, or detailed parts requiring lightweight, strict dimensional tolerances, and high-volume production. In some instances, corrosion resistance and thermal conductivity are not necessities but are usually welcomed benefits that allow for increased design life and improved heat dissipation. Shapes are generally limited to those conducive to uniaxial die compaction; overlaps or undercuts in the direction perpendicular to pressing may not be accommodated; thin walls, narrow spines, and sharp corners are avoided; and the height-to-diameter ratio of parts is kept relatively small. Detailed or spherical surface features that are difficult to form during compaction may be mechanically formed in a secondary operation.

Good candidate parts to produce by additively manufactured aluminum PM are small- to medium-sized, highly complex, or intricately detailed parts requiring lightweight, customization, short production cycles, and low-volume production. There are relatively few limitations for part design. Organic shapes, optimized topologies, thin walls, and hollow or complex internal structures are easily accommodated, allowing for “multiple part consolidation,” weight reduction, and design for function over production. Sharp corners or lines, low-angled features, and overhangs remain manufacturing challenges, and hollow sections must include a drain-hole to remove unused powder after manufacture.

Commercial parts range in size but typically weigh anywhere from a few grams up to several hundred grams. Examples of conventional aluminum PM are numerous and include bearings, bushings, fittings, handles, knobs, levers, brackets, spacers, and housings for consumer durables, lawn/garden equipment, and business machinery as well as gears, valves, shock absorber pistons, and connecting rods for small motors or compressors.^[13–15] The automotive industry is the largest user of conventional PM aluminum where the most compelling application is the camshaft bearing cap (Fig. 2). An estimated 200 million cam caps have been supplied since production began in 1992.^[12,16] More demanding automotive applications involving cam phaser systems and suspension components have been under development.^[17,18] Additively manufactured aluminum PM alloys are well suited for the aerospace, motorsport, health-care, or luxury automotive industries where lower volume production of highly customized products or “rapid prototyping” is required. Perhaps the most ambitious goal is to one day mass produce the aluminum engine block by additive manufacturing.

PROCESSING

Powder Production

The majority of commercial premixes are based on a combination of elemental aluminum powder and alloying elements incorporated as either elemental powder additions or “master alloy” powders rich in alloying elements. Certain alloying elements may also be incorporated into the base elemental aluminum powder as pre-alloyed additions. The mixture of hard elemental or master alloy powders with soft aluminum powder allows for good compressibility. For additively manufactured alloys, compressibility is not a requirement and fully pre-alloyed aluminum powder may be used.

Virtually all PM-grade elemental aluminum powder is produced by air atomization, where an aluminum melt is sprayed through a nozzle by dry compressed air into a collection chamber forming a nodular and irregular powder. Air-atomized aluminum is preferred due to its superior shape, size, and flow characteristics.^[19] Particle size and distribution are controlled by atomization process variables and through post-atomization size classification techniques such as sieving. Commercial PM-grade aluminum powder typically has an average particle size of 40–100 μm with total metallic impurities controlled to less than 0.5 wt%, and special attention is paid to iron and silicon levels.^[20,21] The total oxide content of atomized aluminum is less than 0.3 wt%, which is mostly present as a thin protective layer on the surface of particles.^[22] Inert gas-atomized aluminum alloy powder may be preferred for additive manufacturing since its spherical shape allows smooth and repeatable layers to be spread.

The manner in which alloying elements are incorporated into the premix is equally as important as bulk alloy chemistry. Each commercial premix may have a different processing response depending upon alloying methods, even with the same nominal composition. In general, minor

alloying additions are better incorporated as master alloys, whereas major alloying additions may be incorporated as elemental or master powders; however, care must be taken that the alloying method is not prohibitive to sintering. The particle size and distribution of elemental or master alloy powders should be tailored to ensure homogeneity in the premix and a good processing response.^[23,24] Additive manufacturing generally requires strict local compositional homogeneity to be maintained, and in this case, a single-component, fully pre-alloyed aluminum powder may be more suitable.

Premixes may also contain 1–2 wt% admixed solid lubricant, which aids compaction and helps prevent dusting and segregation. The lubricant must have a low moisture and ash content so as not to interfere with sintering.^[25] The most commercially prevalent lubricant is ethylene bis-stearamide, which is marketed under various trade names.^[26]

Components of the premix are mixed under an inert atmosphere at the plant of manufacture and subject to several quality control checks related to particle size, apparent density, flowability, chemical analyses, and sintering behavior. The apparent density of commercial aluminum premixes generally ranges from 1.0 to 1.4 g cm⁻³.^[27] Oxidation of premixes during storage or transport is normally not an issue.

Compaction

Compaction, or pressing, is responsible for imparting net shape in the PM part and forms the powder premix into a friable “green compact.” Each green compact is characterized by a “green strength” and “green density,” which are determined through a simple transverse rupture test and hydrostatic weighing, respectively. Compaction occurs in closed steel or tungsten carbide dies with force applied through double-action uniaxial pressing of the upper and lower punches by standard mechanical or hydraulic presses.^[11,19] Existing tooling designed for ferrous or cuprous PM may be used. In fact, the excellent compressibility of aluminum powder allows for larger cross-sectional parts to be pressed on the same equipment (Fig. 3). Characteristics of the powder premix such as flow rate, apparent density, and compressibility are necessary to design the appropriate die fill and tooling motions.

In the basic compaction sequence, powder is allowed to flow from a hopper into the die, the upper punch is inserted, the desired pressure is applied, the upper punch is removed, and, finally, the lower punch is raised to eject the green compact. The sequence is fully automated with high production rates of several tens of parts per minute capable on a single press. Powder compaction occurs in several stages as pressure is increased: particle rearrangement, local deformation, homogeneous deformation, and bulk compression.^[1] The regime of these stages is seen in the “compaction curve” that characterizes a powder

Fig. 3 Compaction curves for some commercially available aluminum and ferrous PM materials^[28–31] (also refer the unpublished work of the present authors)

premix through the observation of green density versus compaction pressure (Fig. 3).

For aluminum PM alloys, pressing to 85%–95% theoretical density is desirable; higher compaction pressures cause pressure cracks, lead to blowholes during debulking, and create large contact areas that interfere with sintering. The good compressibility and the nodular/irregular shape of air-atomized aluminum powder allow for good particle interlocking and yield compacts with high green strength so that handling prior to sintering is not normally a problem.^[26]

Alloy additions generally not only decrease the compressibility of aluminum powders (Fig. 3), but also decrease ejection force by helping dislodging aluminum particles that have adhered to the die wall. The internal lubrication in the premix is essential to reduce friction and prevent seizing and galling of the die.^[11] Friction against the die wall and die face can never be entirely eliminated and always results in a three-dimensional green density gradient throughout the compact.^[1]

Sintering

Due to the high reactivity of aluminum metal, sintering is an especially important step in the production of aluminum PM parts and presents some of the greatest challenges and differences between PM processing of aluminum and less reactive metals such as iron or copper. The refractory oxide layer on the surface of aluminum powder particles is prohibitive toward sintering and cannot be reduced by conventional furnace atmospheres, yet must be disrupted to enable the highest quality sintering of aluminum metal. To achieve this, virtually all commercial aluminum PM alloys are “liquid-phase sintered”—that is, sintered in the presence of liquid phase(s) which serve to assist in disrupting the aluminum oxide layer and enhance densification.^[17,19] Liquid phases that are present throughout the duration of sintering are said to be “persistent,” whereas those that are present only temporarily are said to be “transient.” Detailed

information regarding liquid-phase sintering is presented elsewhere.^[1,32–34]

In aluminum PM alloys, the liquid phase(s) are formed as a result of partial melting or contact melting between the components of the premix, and their existence may be transient or persistent in nature. Magnesium is usually a key component in the liquid phase and plays a critical role by reducing the aluminum oxide layer on aluminum particles via formation of spinel (MgAl_2O_4) and acting as a local oxygen getter to enable the sintering of bare aluminum metal.^[35–37]

Sintering must be conducted in a nonoxidizing atmosphere to ensure that active surfaces brought about by liquid-phase sintering do not immediately reoxidize. Nitrogen is the preferred atmosphere for industrial sintering of aluminum PM alloys as it offers the best sintered properties, is economical in bulk quantities, and requires no special handling, gas regeneration, or adsorbent drying.^[38–40] The dew point is usually kept below -40°C ; at higher moisture content, sintered properties diminish sharply. The superior response induced by nitrogen atmospheres is due to a densification event related to the formation of individual nanoscale aluminum nitride (AlN) crystals inside pores.^[41,42] The formation of aluminum nitride locally consumes nitrogen and creates a pressure differential that can destabilize the meniscus forces of persistent liquid phases, leading to “pore filling”.^[43] Detailed thermodynamic analyses of sintering aluminum under nitrogen have been presented elsewhere.^[34,40]

In commercial practice, sintering typically takes place in a continuous muffle-type furnace with a wire-mesh belt conveyor;^[19,26] a schematic is shown in Fig. 4. The sinter cycle may be divided into three stages: “de-lubrication,” sintering, and cooling. In the de-lubrication stage, also referred to as “de-waxing” or “burn-off,” the solid lubricant is removed from compacts in the vapor phase at temperatures between 350°C and 430°C for

15–30 min.^[40] In the sinter zone, precise control of temperature and dew point is necessary. Most commercial aluminum PM alloys are sintered between 580°C and 640°C for 15–60 min.^[40] The sintering temperature is controlled to within $\pm 5^\circ\text{C}$, and the temperature across the belt width does not vary more than $\pm 3^\circ\text{C}$.^[19,26] Throughout the furnace, directed nitrogen curtains are arranged to prevent volatiles from entering the sinter zone and may be preheated to maintain thermal stability (Fig. 4). In the cooling zone, parts enter a water-jacketed section of the furnace and are cooled under a protective atmosphere of nitrogen. Production rates of a single furnace are in the range of 1000–2500 parts per hour, or 20–120 kg per hour, depending on the part shape and size as well as the belt width.^[38,40]

Additive Manufacturing

Additive manufacturing directly consolidates aluminum PM alloys from powder to a net- or near-net-shape component. Before manufacturing takes place, a detailed, three-dimensional, digital model of the component must be created. The digital model is deconvoluted into successive two-dimensional layers used by an additive manufacturing system to produce the component in an enclosed “build chamber.” Commercial systems for processing aluminum PM alloys typically use a fiber laser to “selectively laser sinter” or “selectively laser melt” a thin layer of powder, as shown schematically in Fig. 5. The laser is focused on a discrete point and precisely directed with mirrors to scan the powder bed in predetermined areas that build a layer of the component. The build platform is then incrementally lowered, and a counter-rotating roller spreads the next layer of powder from a feed cartridge over the build platform (Fig. 5). After a cooldown period, the finished build is removed from the powder bed and unused powder is recycled for a new build. Detailed information

regarding selective laser sintering and selective laser melting is available elsewhere.^[2,44,45]

Local densification of aluminum PM alloy powder must occur through either liquid-phase sintering or, more preferably, full melting, as the tenacity of its oxide film precludes effective solid-state sintering.^[45] To this end, the laser is used to generate a local “melt pool” of liquid alloy in each area of focus before advancing; however, the presence of liquid phase alone does not guarantee good consolidation. To achieve the highest quality manufacture, metallic bonds must be formed between successive layers in the component, despite the oxide layer between them. As it is practically impossible to maintain bare aluminum metal in the bulk atmosphere of the build chamber, a different approach must be used. By maintaining the depth of the melt pool greater than the layer thickness, the preceding layer is partially remelted and its oxide layer disrupted by Marangoni convection in the melt pool.^[46] The presence of magnesium in the melt pool is probably beneficial in disrupting the oxide layer, although its role has not yet been firmly established.

Nitrogen and argon are suitable atmospheres for the build chamber. The atmosphere should be nonoxidizing, but beyond this, the response is insensitive and neither atmosphere appears to have a strong role in consolidation.^[47] Processing response, however, is sensitive to a number of laser- and scan-related parameters.^[45,48,49] Laser power and beam diameter determine the “laser energy density,” which must be maintained in unison with the scan rate to deliver the appropriate amount of energy for sintering or fusion. If the energy input is too high, loose powder solid-state sinters to the surface of components causing “part growth”. Too the high-energy input may also transform the melt pool into a non-wetting sphere in a phenomenon called

“balling”.^[2] The optimum energy input is determined by properties such as absorptivity, enthalpy increment, and layer thickness for the alloy. If blended powder premixes are used, the enthalpy of mixing between components must also be considered.

Major concerns in laser consolidation of aluminum PM alloys are the natural anisotropy resulting from the piecemeal manufacture and residual internal stresses resulting from rapid local heating and cooling rates.^[50] If unchecked, these may lead to shape distortion, cracking, and delamination. Residual stress and anisotropy are partially mitigated through “scan strategy” but cannot be totally eliminated.^[45] To maintain near-net-shape manufacture, components must be rigidly consolidated directly to a substrate plate at the start of the build and supports incorporated into the design to prevent distortion, which must be removed in a secondary operation. Another approach is to preheat the powder bed; however, this may induce solid-state sintering in the bed, reducing powder recyclability and exacerbating part growth. If ductility is a major concern, a stress-relieving partial anneal may be performed in a secondary operation.

Secondary Operations

Sintered aluminum PM alloys are highly responsive to a number of secondary operations involving mechanical, thermal, machining, joining, and surface finishing treatments.^[11] The excellent formability of aluminum allows for sintered compacts to be “repressed” in a die or forged with ease.^[51,52] “Sizing” compacts by repressing in a die to improve dimensional tolerances is common as the dimensional instability induced by liquid-phase sintering is generally considered excessive.^[17] Typically, sizing involves a plastic deformation of 1%–5% and may offer secondary benefits of improved physical and mechanical properties. Repressing may also be used to “coin” detailed features into the surface of parts if designs are incorporated into the die face. Any repressing or cold forming operations are usually performed within 24 h of sintering or after solution heat treatment when parts are in a ductile state.^[12]

Aluminum PM alloys respond to thermal treatment in a similar manner to wrought or cast aluminum alloys, and standard heat treatment procedures may be adopted for PM aluminum.^[19] Quenching in brine, or other aggressive media, should be avoided as these may become entrapped in residual surface porosity and lead to corrosion. The machinability of aluminum PM material is excellent and superior to wrought material with respect to chip-breaking characteristics and stringer buildup.^[15] Joining is usually accomplished through press-fitting or staking, but adhesive bonding, brazing, soldering, or joining by threaded fasteners is also possible.^[15] In additively manufactured parts, the base substrate and supports are removed by milling, machining, or other cutting techniques that unfortunately leave witness marks.^[2]

Numerous surface treatments may be applied to aluminum PM alloys to improve material properties or appearance.^[53] Residual surface porosity may be sealed through oil or resin impregnation using soaking or vacuum methods. Oil contained in porosity may provide “self-lubrication” during service. Resin impregnation may be used to improve pressure tightness, fracture toughness, corrosion resistance, or response to plating and machining operations; however, it prohibits any subsequent heat treatment operations. Shot peening may be used as a cold working technique to close open surface porosity and induce residual compressive stress on the surface, improving resistance to corrosion and fatigue.^[53–55]

Most surface finishing operations can be applied to aluminum PM alloys, including chemical cleaning, mechanical finishing, anodizing, coloring, plating, conversion coating, and painting.^[56,57] Finishing operations involving aggressive solutions may damage material of low density, and in these cases, it may be necessary to neutralize the trapped electrolyte or seal surface porosity, for example, by resin impregnation or repressing, prior to finishing. The general finishing sequence involves a vibratory finish for “deburring” and smoothing, deoxidizing to remove surface contamination, burnishing to provide a lustrous appearance, and drying.^[57] For repressed or machined parts, a pre-cleaning step is necessary to remove any oil or lubricant residues. Surface finish may be especially poor for additively manufactured material due to powder adhesion and “stairsteps,” and preliminary sandblasting may be required.^[2] Conventional procedures for anodizing, coating, or painting may be used for aluminum PM alloys. The presence of surface porosity tends to result in thinner, less continuous coatings, which are more susceptible to blistering compared to wrought or cast material.^[56]

STRUCTURE AND POROSITY

2xxx Series Alloys

The 2xxx series aluminum PM alloys contain copper as the major alloying element and may include minor alloy additions of magnesium, silicon, and tin. Most commercial alloys are based on the wrought 2014 system; however, alloys with lower copper-to-magnesium ratios based on the wrought 2024 system have also been developed.^[58] The relatively moderate amount of alloy additions allows good compressibility of these premixes. For the 2014 system, compaction pressures of 200–400 MPa are capable of achieving green densities of 92%–96% and green strengths of 5–16 MPa.^[11,27,59,60] In the 2024 system, compressibility is slightly reduced due to the higher magnesium content so that compaction pressures of 200–400 MPa achieve green densities of 89%–94% theoretical.^[61]

Sintering is usually conducted at 590°C–610°C for 15–30 min,^[58–60] during which anywhere from 10 to 20 wt%

persistent liquid phase may be present.^[34,60] Generally, the alloys based on the 2014 system expand up to 4% in the direction of uniaxial pressing, which limits their sintered density to 91%–95% theoretical.^[27,59,62,63] The 2024 system shows better densification with sintered densities ranging from 95% to 98% theoretical and dimensional shrinkages of 1%–3%.^[58,61]

Liquid-phase sintering and densification begin during heating to the sintering temperature, where various transient and persistent liquid phases are formed by partial melting of master alloy powders or contact melting between components of the premix.^[59,61] The formation of liquid phases may coincide with the beginning of volume expansion events. The persistent liquid is based on the Al–CuAl₂ eutectic with magnesium and silicon acting to lower the eutectic temperature and increase the total amount of liquid phase. Minor alloy additions of tin also enhance liquid-phase sintering.^[64–66] Densification is primarily brought about by particle rearrangement due to capillary forces. During holding at the sinter temperature, grain growth is able to proceed by the solution-reprecipitation process. During this stage, a polyhedral structure is formed, pores become rounded, and the microstructure coarsens with longer sintering times.

After sintering, the primary structural features include closed, rounded porosity and a polyhedral grain structure with intermetallics located along grain boundaries from the nonequilibrium solidification of the liquid phase^[27,58,67] (Fig. 6). The intermetallics along grain boundaries primarily consist of θ -phase (CuAl₂), S-phase (CuMgAl₂), or other constituents containing these elements plus silicon,^[58,62] but iron- and tin-containing compounds may also be present.^[65] The S-phase is more apparent in alloys with lower copper-to-magnesium ratios, such as the 2024 system.^[58] Iron-containing intermetallics are formed due to

Fig. 6 Optical micrograph of Alumix 123-T1 (Al–4.5Cu–0.5Mg–0.7Si; etched) showing a polyhedral grain structure with various copper- and iron-containing intermetallics located along grain boundaries. The black intergranular regions are pores

the segregation of iron impurities in the aluminum powder to the liquid phase during sintering.^[68] If present, tin may exist in discrete phases throughout grain boundaries or in high magnesium alloys, as Mg_2Sn .^[65,66] The matrix grains consist of α -Al solid solution containing a few weight percentage of copper and small amounts of magnesium and silicon, with the composition depending on the sintering temperature and bulk copper content of the alloy. There may be finely dispersed constituents in the center of grains originating from the dendritic structure of atomized aluminum particles that are not completely transformed during sintering.^[26]

Heat treatment is performed by solutionizing at 490°C – 500°C for 1 h followed by natural or artificial aging.^[61,62,69,70] During solutionizing, copper is dissolved into solid solution with aluminum, whereas iron-containing phases are transformed to acicular, needlelike compounds such as $\beta(\text{FeCu})$ (Cu_2FeAl_7).^[62] Alloys based on the 2014 system may be artificially aged at 160°C for 16–18 h,^[62,69,70] whereas alloys based on the 2024 system may be artificially aged at 190°C for 10 h.^[61] Precipitation hardening is similar to analogous wrought alloys and may be associated with the formation of strengthening derivatives of θ -, S-, β - (Mg_2Si), or Q-phase ($\text{Cu}_2\text{Mg}_8\text{Si}_6\text{Al}_5$).^[69–71] Alloys strengthened by S-phase precipitates are more amenable to sizing or other cold work, as S-phase precipitates nucleate on dislocations that are formed during cold working.^[71] Minor alloy additions of tin may slightly reduce age hardenability; however, the effects are largely overcome by the improvements in sintered density achieved through such additions.^[70,71]

4xxx Series Alloys

Aluminum PM alloys containing silicon as the major alloying element are designated by the 4xxx series. The PM process is more conducive to processing alloys with higher silicon contents as these are not restricted by the same production difficulties, such as working or machining, as wrought or cast alloys. These are also the most developed aluminum PM alloys for additive manufacturing, as most of the properties that make them good casting alloys also make them well suited for additive manufacturing. Most commercial alloys are based on hypereutectic systems containing up to 15 wt% silicon and are compositionally similar to wrought alloy 4032 or cast alloy 390.^[31] Hypoeutectic alloys containing 6 wt% silicon have also been developed.^[72,73]

Major alloy additions of silicon significantly reduce the compressibility of these premixes, and relatively high compaction pressures of 500–700 MPa are necessary to achieve modest green densities ranging from 90% to 93% theoretical.^[31,60,74–76] The relatively poor compressibility means that there may be more pronounced density gradients in the green compact compared to other alloy systems.^[60] Despite the low green densities, these premixes

display good particle interlocking and develop relatively high green strengths ranging from 11 to 25 MPa.^[31,72]

Liquid-phase sintering of 4xxx series alloys is extremely sensitive to temperature. Aluminum and silicon form a simple eutectic system with silicon exhibiting limited solid solubility in aluminum but appreciable solubility in the liquid phase, which means that major alloy additions of silicon may generate a prohibitive amount of liquid during sintering if the temperature is not carefully controlled. Most alloys are best sintered in the narrow temperature range of 555°C – 565°C and require relatively longer sinter times of 20–60 min,^[31,60,72,73,75–77] during which anywhere from 15 to 40 wt% persistent liquid phase may be present.^[34,60] The long sinter times may allow for good densification with sintered density ranging from 92% to 99% theoretical and dimensional shrinkages of 2%–6%.^[31,75]

Although sintering is conducted at temperatures below the aluminum–silicon eutectic of 577°C , a controlled amount of liquid phase is generated through minor alloy additions of copper and magnesium. During heating, transient and persistent liquid phases are generated through partial melting of master alloy powders, which induce densification in at least two stages.^[31,72,74] In the first stage, a rapid densification is brought about by particle rearrangement due to capillary forces. During holding at the sintering temperature, a second, slower densification process occurs due to secondary rearrangement or solution-reprecipitation.

The sintered microstructure consists of a polyhedral aluminum grain structure with a dispersion of silicon crystals and intermetallics located along grain boundaries^[31,75] (Fig. 7). The size of the silicon crystals depends upon the silicon content of the alloy as well as the alloying method in the premix. For the hypereutectic alloys, some primary silicon crystals present in the premix are retained after sintering, so it is advantageous to incorporate silicon in the premix as an atomized master alloy powder, which presents a refinement of this feature.^[77] In the hypoeutectic alloys, proportionally more silicon may be expected to be in the liquid phase, and after sintering, the majority of silicon crystals are situated along grain boundaries.^[72,73] Other intermetallics along grain boundaries consist of a combination of alloying elements or impurities that enter the liquid phase, such as copper, magnesium, silicon, and iron.^[31] The dominant copper-containing phase is believed to be θ -phase (CuAl_2), whereas iron may form ternary Al-Si-Fe compounds.^[31,72,73,75] The aluminum grains consist of α -Al solid solution containing copper, magnesium, and silicon.^[31]

Heat treatment procedures include a solutionization at 490°C – 520°C for 1 h followed by a cold or warm water quench, and natural aging at room temperature or artificial aging at 160°C – 170°C for 8–10 h.^[31,77] The solutionizing temperature should be chosen with consideration of the alloy solidus. Precipitation hardening is primarily due to the formation of θ -phase derivatives although, based

on the chemistry of the alloy, the formation of β -phase (Mg_2Si) derivatives may also play a role.^[31] A pseudo-solutionization step may be incorporated into the sinter cycle by furnace cooling to 460°C–500°C before gas quenching to allow for modification of the type and morphology of intermetallics and achieve superior strength without affecting ductility.^[78]

Additive manufacturing of the 4xxx series alloys is in the advanced stages of commercial development. Most of the commercial alloys for additive manufacturing are closer to eutectic composition and contain minor alloy additions of magnesium or copper. Major alloy additions of silicon reduce the viscosity and solidification shrinkage of the melt pool and are kept close to the eutectic composition to depress the liquidus and minimize the melting range.^[45] Minor alloy additions of magnesium reduce the surface tension of the melt pool and probably help to disrupt aluminum oxides. There has been considerable effort in developing “process maps” and optimizing process parameters, such as scan strategy, layer thickness, laser powder, and powder bed temperature, for property development while minimizing the build time.^[45,48,49] As-built densities are typically over 99% theoretical, but dimensional accuracy is not quite as strict as conventional PM aluminum where parts are formed in a rigid die. As-built microstructures are usually highly refined, but melt pool borders and scan tracks remain visible. Melt pool interiors show a fine distribution of eutectic silicon among fine epitaxial aluminum grains supersaturated with silicon.^[79] There is also an anisotropy in the microstructure depending not only on the build pattern but also on the height of the component

with a tendency for coarsening near the bottom of components as this area gradually retains heat from the building process.^[45] Various heat treatments have been developed to reduce residual stresses, improve ductility, or age harden.^[79]

6xxx Series Alloys

The 6xxx series aluminum PM alloys contain a combination of magnesium and silicon as the principal alloying elements and are relatively lean alloys with the total alloy content generally around 2 wt%. The alloy system is based on the magnesium silicide compound (Mg_2Si), or β -phase, which requires a stoichiometric magnesium-to-silicon ratio of 1.73 by weight; however, in practice, most systems contain either an excess of magnesium or silicon.

These premixes display excellent compressibility due to the low amount of alloy additions, but this also reduces the green strength. Compaction pressures of 200–400 MPa may achieve green densities of 92%–95% theoretical with green strengths ranging from 6 to 10 MPa.^[11,53,80,81]

Due to their relatively low alloy content, sintering must be conducted at higher temperatures in order to generate sufficient amounts of liquid phase. Generally, sintering takes place at 620°C–640°C for 15–30 min,^[53,81] during which anywhere from 5 to 20 wt% persistent liquid phase may be present.^[34,60] These alloys generally densify well with sintered density ranging from 95% to 99% theoretical and dimensional shrinkages up to 2%.^[53,81]

During heating, various transient and persistent liquid phases are formed due to partial melting of master alloy powders or contact melting between components of the premix.^[53,81–83] The generation of liquid phases coincides with volume expansion.^[83] At the sintering temperature, persistent liquid phases are present, which probably induce densification by particle rearrangement due to capillary forces.^[53,81] The relatively lower amount of persistent liquid phase suggests that these alloys may be more sensitive to oxidation or lubricant residues which disturb sintering mechanisms.

The sintered microstructure consists of polyhedral aluminum grains with rounded porosity and a distribution of intermetallics along grain boundaries^[67] (Fig. 8). The matrix grains consist of α -Al solid solution containing copper, magnesium, and silicon.^[53,81] The predominant intergranular intermetallic is β -phase; however, there are also iron-containing intermetallics as this impurity segregates to the liquid phase during sintering and forms intermetallics during solidification.^[53,62,81,82] In alloys containing more silicon than is needed for β -phase, elemental silicon particles may be present along grain boundaries.^[26]

Heat treatment is performed by solutionizing at 530°C for 1 h followed by a cold water quench and natural aging at room temperature or artificial aging at 160°C for 18 h.^[53,81] During solutionization, heat treatment dissolves β -phase,

but insoluble iron-containing intermetallics remain in intergranular regions.^[53,62,81] Precipitation hardening is primarily based on the formation of β -phase derivatives, although in some alloys, minor alloy additions of copper may also contribute some hardening effect.^[26]

7xxx Series Alloys

The 7xxx series aluminum PM alloys contain zinc as the major alloying element. Aluminum-zinc alloys have relatively poor castability so PM is an attractive alternative for the production of net-shape components. Most commercial alloys contain zinc additions of 5–8 wt% and are based on the aluminum-zinc-magnesium alloy system analogous to wrought alloy 7075.^[84] The relatively high amount of alloy additions reduces the compressibility of these premixes to some extent. Compaction pressures of 400–600 MPa are necessary to achieve green densities of 89%–94% theoretical with green strength ranging from 10 to 16 MPa.^[61,84–91]

The high solubility of zinc in solid aluminum metal alludes to the transient nature of the liquid phases present during sintering of the 7xxx series alloys. As zinc is a relatively low-melting metal, transient liquid phases rich in zinc may form and disappear early in the sinter cycle and are especially sensitive to processing parameters such as alloying method, particle size, and heating rate. The high zinc content of the eutectic requires sintering to be conducted at higher temperatures, where the solid solubility of zinc in aluminum is reduced and a sufficient amount of liquid phase may be generated.

Sintering is usually conducted at temperatures of 590°C–620°C for 15–30 min.^[61,84,86–89,91] During

sintering, anywhere from about 10–30 wt% persistent liquid phase may be present.^[34,60] The sinter response is good with sintered density ranging from 95% to 99% theoretical and dimensional shrinkages of 2%–6% in all directions.^[61,84,87–91]

During heating, volume expansion events occur, which coincide with the formation of various transient and persistent liquid phases from melting of elemental or master alloy powders.^[61,85,88,90,92–94] Eventually, the volume of persistent liquid becomes great enough that densification occurs by particle rearrangement.^[61,85,90,94,95] Alloy additions of copper and tin play a key role in the formation of persistent liquid phases and densification.^[93,94] Due to the relatively high volatility of zinc, there may be a depletion of this element near the surface of compacts after sintering,^[89,91] and the positioning of compacts and gas flow in the sintering furnace may have an effect on the sintered density.^[96]

The sintered microstructure consists of polyhedral aluminum grains and small amount of isolated and rounded porosity^[84,90,91] (Fig. 9). The matrix grains consist of α -Al with a significant amount of zinc, magnesium, and copper in solid solution; however, these elements are also present in intergranular phases.^[26,84,88] The principal intergranular intermetallic is η -phase (MgZn_2); however, constituents containing copper, tin, or iron have also been observed.^[62,84,85,88,90,92] Tin may be present in elemental clusters, as Mg_2Sn , or incorporated with other

The points labeled 1, 2, and 3 were assayed with electron probe micro-analysis^[84]

intergranular intermetallics in small amounts.^[84,85,91] Some amount of copper may be expected to be in solid solution with η -phase, but there may also be a small amount of θ - (CuAl_2) or S-phase (CuMgAl_2) constituents.^[26,84] In alloys with higher magnesium contents, the T-phase ($\text{Al}_2(\text{Zn,Cu})_3\text{Mg}_3$) may form as an intergranular constituent.^[85] Iron is an impurity in the base aluminum powder which segregates to the liquid phase during sintering and forms intermetallics during solidification.

Standard heat treatment procedures include solutionization at 470°C for 1–1.5 h, followed by natural aging at room temperature or artificial aging at 120°C–130°C for 24 h.^[61,62,84,87,88,91] During solutionization, η -phase is dissolved in the matrix, but tin- and iron-containing intermetallics remain as insoluble compounds.^[62,84,85] The iron-containing compounds transform into acicular needlelike constituents such as $\alpha(\text{FeCu})$ ($(\text{FeCu})\text{Al}_6$) or $\beta(\text{FeCu})$ (Cu_2FeAl_7).^[85] Precipitation hardening is primary due to the formation of η -phase derivatives—S-phase or its derivatives have not been observed during aging.^[84,91] A pseudo-solutionization step may be incorporated into the sinter cycle by furnace cooling to 520°C followed by gas quenching, which improves tensile strength and corrosion resistance in the T1 temper.^[88]

PROPERTIES AND PERFORMANCE

Tensile, Compressive, and Shear Strength

Most commercial aluminum PM alloys are heat treatable, and, therefore, a range of mechanical properties are available for each alloy system,^[12,97] as shown in Tables 4–6. In the case of additively manufactured alloys, there is a certain anisotropy (Table 6), which is reduced by performing heat treatments. In general, aluminum PM alloys display tensile yield and ultimate tensile strengths (UTSs) that are comparable to their wrought counterparts (Table 7); however, their ductility is generally inferior to wrought alloys due to the presence of residual porosity and residual oxide which act as stress raisers.^[61] The exception are the additively manufactured aluminum PM alloys (Table 6), which, by careful processing, may surpass their wrought counterparts.^[79] As with wrought alloys, macro-hardness may be used as an approximate measure of strength but is strongly affected by porosity and, therefore, usually given as “apparent hardness.”

The available data on compressive yield strength are limited to the 2xxx and 6xxx series alloys and are contradictory; some investigations indicate that compressive yield

strength is virtually identical to tensile yield strength^[52] whereas others suggest it is up to 30% less than tensile yield strength.^[100] The shear strength of some aluminum PM alloys has been determined to be 60%–80% of the values for corresponding wrought alloys, but this is comparable to values for cast aluminum alloys.^[100]

In the T1 temper, strength is strongly affected by the cooling rate which dictates the extent of post-sinter natural aging that occurs.^[27,72,78] Heat treatment to the T6 temper represents the highest strength condition obtainable for a given alloy, but is also accompanied by a decided reduction in ductility. Generally, for material of any temper, a higher sintered density corresponds to improved tensile and compressive properties,^[97,100] and therefore, compaction and sintering steps may influence these properties through their effect on sintered density so long as important microstructural features are not drastically altered. Similarly, by optimizing alloy composition and alloying methods of the premix, sintered density may be increased, leading to significant improvements in strength and ductility.^[98] Ductility in additively manufactured alloys is considerably enhanced by performing stress-relieving heat treatments after building.^[79]

Secondary processing provides an opportunity to further consolidate PM material, enhancing tensile and compressive properties. Standard cold working operations, such as sizing, are implemented primarily to improve dimensional tolerance but also provide modest increases in strength while subsequently reducing ductility.^[19,52,71] Ductility may be restored through heat treatment after cold working. Hot working provides more significant improvements, with tensile elongation increased to 5%–6%, while tensile strength may be increased to levels superior to wrought materials.^[61,77,87,101]

Prolonged elevated temperature exposure above a characteristic temperature leads to overaging and grain growth, which is accompanied by a pronounced reduction in strength.^[102] Generally, aluminum PM alloys display a thermal stability similar to their equivalent wrought alloys, with properties deteriorating between 160°C and 200°C.^[84,102] A 2xxx series aluminum PM alloy with enhanced thermal stability up to 260°C, containing iron and nickel additions and based on wrought alloy 2618, has been developed.^[103]

Impact Resistance

The impact resistance of aluminum PM alloys correlates well to their ductility and, accordingly, may be inferior to wrought alloys.^[97,100] Usually, impact resistance is highest in the annealed temper and lowest in the fully heat-treated T6 temper, with the T4 temper providing a good compromise between the two. Impact resistance is strongly affected by porosity and may be improved by increasing sintered density, especially through hot working after sintering.^[52,100] Cold working, without subsequent heat treatment, tends to reduce impact resistance.^[52]

Impact testing of PM materials is usually conducted using unnotched specimens to obtain results which are within the region of accurate determination for standard instrumentation. For 2xxx and 6xxx series alloys evaluated by ASTM Standard E23, unnotched absorbed energies range from 5.8 to 7.5 J in the T1 temper.^[97,100] For most alloys, a good combination of tensile strength and impact resistance is obtained in the T4 temper, where unnotched absorbed energies range from 7 to 18 J.^[97]

Fatigue Resistance

Without secondary treatment, all aluminum alloys processed by PM contain some amount of residual porosity and residual oxide which act as stress concentrators and reduce fatigue strength. Consequently, the fatigue resistance of aluminum PM alloys is highly dependent upon sintered density and, for additively manufactured alloys, may also be anisotropic. Without secondary operations, the fatigue limit of aluminum PM alloys is usually about 50%–80% that of equivalent wrought alloys, but may be within the range of cast aluminum alloys.^[84,97,100] Fatigue cracks usually initiate at pores or pore clusters near surfaces in tension and first propagate in a transgranular fashion, eventually transitioning to intergranular with continued growth.^[104]

Secondary processing provides an opportunity to improve fatigue resistance through consolidation or heat treatment.^[15,87,97] Cold forming, or T2 tempering, provides improvements in fatigue resistance that scale with the amount of consolidation induced.^[15,52] The highest fatigue resistance is obtained by hot working and full heat treatment, which may improve fatigue life and fatigue limit to values close to or beyond those of equivalent wrought alloys.^[15,51,87,100] Fatigue resistance of additively manufactured aluminum PM alloys is highest after heat treatment and machining.^[105] Shot peening is a promising technique for aluminum PM alloys to close open surface porosity and induce residual compressive stresses at the surface, improving fatigue resistance.^[54,55,91]

Corrosion Resistance

The corrosion resistance of aluminum PM alloys, compared to analogous wrought or cast aluminum alloys, may be inferior unless secondary processing or special treatments are performed. Inferior performance is usually the result of residual open surface porosity, high surface area, and microstructural features, with the magnitude of impact depending upon the density of the PM alloy and severity of the environment. Generally, in higher density PM parts or less severe environments, the difference in corrosion resistance between PM and wrought or cast aluminum alloys becomes minimal.^[97,100]

In addition to the corrosion susceptibilities of traditional aluminum alloys, such as pitting or intergranular corrosion, aluminum PM alloys are naturally susceptible to crevice corrosion due to the presence of residual surface porosity. Electrolytes may become trapped within residual surface porosity and lead to the initiation and propagation of crevice corrosion within the porosity, effectively creating a galvanic cell between the interior of pores and the external planar surface.^[106] In this case, the apparent corrosion rate of the PM alloys may be up to four times that of equivalent wrought alloys, although to accurately determine true corrosion rates, the real surface area and residual open surface porosity must be measured.^[107]

Corrosion resistance is usually lowest in the T1 temper, where residual surface porosity is highest and intermetallics are predominantly located along grain boundaries. This distribution of intermetallics is a fundamental characteristic of liquid-phase sintering but imparts a high susceptibility to intergranular corrosion, stress corrosion cracking, and corrosion fatigue. A similar situation occurs in additively manufactured alloys where localized corrosion occurs at the melt pool borders.^[108]

Secondary processing provides an opportunity to improve corrosion resistance through surface modification. Standard cold forming, or sizing, to the T2 temper improves corrosion resistance by reducing the amount of surface porosity but does not change susceptibility to intergranular corrosion.^[106] Even greater improvements in corrosion resistance may be obtained through hot working operations.^[53,88] Surface treatments such as shot peening, resin or oil impregnation, chemical conversion coating, and anodizing all improve corrosion resistance.^[53,56]

Wear Resistance

It is difficult to characterize wear resistance in standardized testing as the type of wear, materials, and loads may vary greatly depending upon application; however, considering the propensity for aluminum PM in automotive applications such as gears, cams, or pulleys, their sliding wear resistance against themselves and common engineering materials has been studied.^[97] In general, the sliding wear resistance of aluminum PM alloys is lower in the T1 temper and higher in the fully heat-treated T6 temper.^[97] In the T6 temper, the sliding wear resistance of the 2xxx series alloys is close to that of some die cast aluminum alloys.^[97] In abrasive wear tests, 2xxx series aluminum PM alloys perform have similar wear resistance certain die cast aluminum alloys, whereas 4xxx series aluminum PM alloys display exceptional wear resistance superior to many die cast aluminum alloys.^[12]

Wear resistance may be improved through oil impregnation or by anodizing a hard, resistant coating onto the surface of parts.^[56] In oil-impregnated aluminum PM alloys, residual surface porosity is beneficial and acts as a reservoir for lubricating oil, which provides a self-lubricating effect and reduces wear involving sliding movements such as gears or cams.^[12] Residual surface porosity also acts as a site that may trap wear debris, preventing it from contributing to further wear.^[12] Wear resistance of additively manufactured alloys is expected to be equal or superior to many die cast aluminum alloys due to their high hardness and refined microstructure.

Thermal and Electrical Conductivities

The presence of residual porosity in aluminum PM alloys reduces both their thermal and electrical conductivities. Typically, thermal and electrical conductivities of

aluminum PM alloys reach about 95% of the values of their corresponding wrought alloys.^[11,19,100] Under alternating current conditions, the electrical conductivity of aluminum PM alloys may be diminished further and become especially sensitive to surface porosity, rather than bulk sintered density, due to the so-called skin effect where current density is primarily located near the surface.

Thermal and electrical conductivities are strongly influenced by sintered density and the amount of alloying elements in solid solution with aluminum. PM processing conditions or secondary operations that improve bulk sintered density or reduce the amount of alloying elements in solid solution with aluminum generally lead to improvements in conductivity. Thus, repressing or heat treatment after sintering tends to increase thermal and electrical conductivities.^[11,100] Novel aluminum PM alloys based on the ternary aluminum–magnesium–tin system have been developed, which show enhanced thermal conductivities up to $225 \text{ W m}^{-1} \text{ K}^{-1}$ at 20°C .^[109] At present, the most thermally conductive commercial aluminum PM alloys are the 6xxx series that display thermal conductivities up to $170 \text{ W m}^{-1} \text{ K}^{-1}$ at 20°C .^[11]

FUTURE DEVELOPMENTS

Although many of the fundamental problems and challenges of working with aluminum powder have been overcome, there is still significant progress to be made with many aspects of the PM process and their effects on material properties and performance. Although many developments have been aimed to improve and understand PM processing response, the result of material properties and performance is sometimes considered secondary. However, the material properties and performance of current aluminum PM alloys are the major limiting factors in their use for more demanding applications. Improvements to properties such as ductility and modulus, and performance in environments involving fatigue, corrosion, or high temperature may expand the use of aluminum PM alloys. Property and performance improvements may be accomplished through many aspects of the PM process, from the design of alloy systems to powder production, alloying methods, consolidation methods, or secondary processing.

With regard to alloy systems, there has been little development on aluminum–lithium or aluminum–copper–lithium PM alloys. If the reactivity and volatility of lithium may be safely controlled, these materials may offer improved stiffness. The effect of iron impurities in aluminum PM alloys has not been given much attention either. Research involving iron correctors, such as manganese, may prove promising to inhibit the formation of embrittling iron compounds and improve ductility. The production and utilization of nanopowdered aluminum or

ceramics in aluminum PM alloys is an interesting possibility to produce alloys with refined microstructures, provided the oxide content of such aluminum powder is not prohibitive. New or unconventional PM alloy chemistries may be possible through doping the base aluminum powder with minor alloy additions, which has been demonstrated for transition metals, to achieve enhanced material properties without significantly affecting PM processing response.

Additively manufacturing aluminum PM alloys is extremely promising, and a revolution is under way as key patents have begun to expire and the technology becomes smaller, faster, and less expensive. These alloys are not bound by the same limitations in chemistry as conventional aluminum PM alloys. There is the possibility of producing non-heat-treatable aluminum PM alloys, such as the aluminum–manganese or aluminum–magnesium alloys, and design of new alloys specifically for additive manufacturing. In fact, this technology seems particularly well suited for developing refined aluminum–transition metal alloys for elevated temperature applications where residual stresses would naturally be eliminated. There are, however, remaining challenges for additively manufactured aluminum PM alloys. Although many look to other additively manufactured materials for insight, there is also much to be learned by analogy to the conventional aluminum PM alloys and the rapid solidification processed aluminum PM alloys of the past.

Spark plasma sintering and powder forging are other promising consolidation techniques for aluminum PM alloys, which may allow for more refined microstructures with improved strength and ductility. The development of cost-effective secondary processing is another area of interest. The incorporation of a solution treatment into the sinter cycle before quenching appears to be useful for improving strength without more expensive secondary heat treatments.

CONCLUSIONS

PM processing is a commercially established manufacturing technique to produce net- or near-net-shape aluminum alloys that compete with traditional wrought and cast aluminum alloys. Aluminum PM alloys may be produced by the conventional PM process or through additive manufacturing. Most commercial aluminum PM alloys are based on the 2xxx, 4xxx, 6xxx, or 7xxx series alloy systems for wrought aluminum and always contain alloy additions of magnesium, which are necessary to reduce the aluminum oxide layer on powder particles during sintering.

In the conventional PM process, aluminum PM alloy premixes are prepared from a mixture of elemental aluminum powder, alloying element powder, and lubricant powder. The powder premix is uniaxially compacted in

closed dies to form a green compact, which is then sintered in a continuous wire-mesh belt furnace under dry nitrogen. Virtually all aluminum PM alloys are liquid phase sintered to help disrupt the aluminum oxide layer on particles and allow for good interparticle bonding and densification. Liquid-phase sintering allows for relatively short sintering times but also induces dimensional distortion. After sintering, a number of secondary operations involving mechanical, thermal, and finishing treatments may be performed. Sizing is a standard secondary operation that uses repressing to improve dimensional tolerances.

In additive manufacturing, aluminum PM alloy powder is directly consolidated based on a three-dimensional, digital model of a component. Consolidation occurs in a layer-by-layer manner whereby a thin layer of powder is selectively laser sintered or selectively laser melted in predetermined areas after which a new layer of powder is laid. A number of laser and scan-related parameters precisely control the consolidation process so that underlying oxide layers are disrupted and strong metallic bonds are developed. Additive manufacturing allows great freedom in design but also develops residual internal stresses and a certain anisotropy in components. Support structures are usually incorporated to prevent shape distortion from residual stresses and must be mechanically removed in a secondary operation. Other secondary operations involving mechanical, thermal, and finishing treatments may also be performed. Heat treatments are standard secondary operations used to reduce residual internal stresses and anisotropy.

The structure and porosity of aluminum PM alloys depends upon alloy chemistry and powder characteristics as well as PM processing conditions for compaction, sintering, additive manufacturing, and secondary operations. Virtually all material properties of aluminum PM alloys are affected by their residual porosity, which may reduce their performance to levels inferior to wrought or cast aluminum alloys. In many cases, improvements in the properties and performance of aluminum PM alloys are associated with higher sintered densities, whereas in other cases, properties are more strongly affected by residual open surface porosity, rather than bulk sintered density. The complete elimination of residual porosity is not as important as understanding, anticipating, and controlling its presence. Secondary processing provides an opportunity to increase density and close residual surface porosity, improving many material properties and performance. With careful PM processing, the properties of aluminum PM alloys may surpass those of wrought aluminum alloys.

ACKNOWLEDGMENTS

The authors express their sincere thanks and gratitude to the Metal Powder Industries Federation for granting

permission to publish the photograph of the aluminum PM cam cap; Dr. Abdulwhab Ibrahim for providing the Alumix 321 material used for microscopy; Jessu Joys of AMPAL, Inc., for kindly gathering and providing technical data regarding material properties; and, finally, the Natural Sciences and Engineering Research Council of Canada (NSERC) for financially supporting this work.

Abstract

The transportation industries are constantly striving to achieve minimum weight to cut fuel consumption and improve overall performance. Different innovative design strategies have been placed and directed toward weight saving combined with good mechanical behavior. Among different materials, aluminum-based alloys play a key role in modern engineering and are widely used in construction components because of their lightweight and superior mechanical properties. Introduction of different nanostructure features can improve the service and the physical properties of such alloys. In this study, alloy AA2195 has been selected and characterized by means of transmission electron microscopy and atom probe tomography. Quantitative chemical analyses reveal that applying the rolling deformation on the specimen causes the uniform distribution of different platelet precipitates such as $T_1(\text{Al}_2\text{CuLi})$ and $\theta'(\text{Al}_2\text{Cu})$, which increases the hardening behavior of such alloys. Applying a plastic deformation on such alloys has been highlighted as an important engineering tool for the manipulation with second-phase precipitates in the microstructure. In this study, the findings of the characterization analysis were translated to construct a robust microstructure with an excellent hardness behavior (hardness value of 209 HV) by applying a low-energy consumption, cost-effective method.

Keywords: Aluminum alloys; Atom probe tomography; Hardening; Plastic deformation; Precipitates.

INTRODUCTION

In response to the demands of various industries for light structural materials, different aluminum lithium alloys have been developed.^[1] These alloys are commonly selected because they exhibit an enhanced strength/weight ratio and therefore are typically applied as functional materials with high performance in the aerospace and automobiles industries. Economically, Al–Li alloys are only three times as expensive as conventional aluminum alloys, whereas competing hybrid materials can be up to 10–30 times more expensive.^[2] In the context of high fuel prices and fierce competition between composite, hybrid materials, and aluminum alloys, different Al–Li–Cu alloys have been developed to overcome most of the technical issues associated with the formerly available materials.^[3] In the space industry, for instance, Al–Li–Cu based alloys are the candidate material for the construction of launch-vehicle liquid-propellant tanks because the ductility and toughness of the alloy are not affected at the lower temperatures. These alloys are known to be strengthened through precipitation hardening and are attracting strong interest in the framework

of the development of new alloys, particularly for aerospace components.^[4] The current study selects one of the widely used Al–Li–Cu alloys from the Weldalite family,^[1] namely, the commercial AA2195. This alloy was developed to replace the AA2219 alloy, which was conventionally used in the US space shuttles.^[5] AA2195 is considered to be the third generation of Al–Li alloy. It receives considerable attention from both industrial and scientific communities because of its attractive properties. It has low density, high stiffness, very high strength, good damage tolerance and good weldability. All of these characteristics make this alloy an appealing choice for direct and engineered substitution in all weight-critical applications. AA2195 has been used widely in high-performance military and commercial aircraft. Recently, this material has been successfully used by the National Aeronautics and Space Administration (NASA) in space shuttles for super lightweight cryogenic tanks, which resulted in a significant increase in payload capacity.^[6] This class of alloy is able to achieve superior mechanical properties in the stretched and artificially aged condition (termed as T8), artificially aged condition (termed as T6), and naturally aged condition (termed as T4).^[7]

The presence of various micro-alloying elements at a variable volume fraction and adequate subsequent treatment causes the precipitation of different possible phases within the Weldalite family such as $T_1(\text{Al}_2\text{CuLi})$, $\theta'(\text{Al}_2\text{Cu})$, $\beta'(\text{Al}_3\text{Zr})$, and $\delta'(\text{Al}_3\text{Li})$. The T_1 phase is thought to be responsible for the bulk precipitation strengthening. This phase is hexagonal with symmetry P6/mmm and forms as platelets on the {111} plane of the Al matrix. When embedded in the Al matrix, it is usually thin (~1.3 nm in thickness). The thickness is equal to the stacking of only five {111} atomic planes. On the other hand, the T_1 platelets can have a very large extension, between 50 and 100 nm, without losing their coherency with the matrix.^[8] Despite the high coherency of the T_1 precipitates, it has been proved to be remarkably difficult to nucleate homogeneously. To overcome this issue, plastic deformation must be applied before aging. In this system, plastic deformation increases the precipitation kinetics by one order of magnitude.^[9] It has been concluded that the precipitation of this phase is also difficult without the presence of secondary alloying elements such as Mg and Ag, which can offer nucleation sites within the matrix for this phase.^[10] The potential role of these micro-alloying elements is to simulate the nucleation of an exciting precipitate by reducing the interfacial energy between precipitate and matrix and by clustering together; hence, their clusters of atoms act as heterogenous nucleation sites for the new precipitates.^[11] Once again, additional micro-alloying elements must associate with applied plastic deformation prior to artificially aging to increase the number of nucleation sites for the T_1 phase. An expected result of this thermomechanical treatment is the promotion of a uniform distribution of a heterogeneously nucleated T_1 phase. The T_1 platelets usually act as non-shearable obstacles to dislocation motion and promote slip homogenization.^[12] The T_1 phase coexists with the $\theta'(\text{Al}_2\text{Cu})$ phase, which lies as plates on the {100} matrix planes. This phase is dominant in the early stage of the heat treatment at elevated temperatures of 588–644 K.^[13] In addition to the T_1 and θ' phases, Zr forms coherent spherical $\beta'(\text{Al}_3\text{Zr})$ precipitates with L_{12} structure that is already formed during the alloying process within the melt. The presence of β' particles is designed to control the grain structure and degree of crystallization after the solidification of the ingot.^[3] Finally, the $\delta'(\text{Al}_3\text{Li})$ is usually reported to precipitate upon quenching from the melt for alloy compositions higher than 5 at.% Li in the matrix.

The practical application of Al-based alloys needs intensive research on the development and engineering of such important functional material. Although alloying and

age-hardening effects were discovered at the beginning of the last century and have been used as the main approaches to improve the strength of Al alloys, it has been recently realized that a better improvement in the microstructure of the alloy and hence its mechanical properties can be achieved by applying several engineering methods.^[14] One of these methods is plastic deformation. This operation leads to phase transformation in the material.^[15] The scientific basis of this approach, applying plastic deformation, is that the atomic movements driven by an external action, i.e., deformation, are higher than those of conventional thermal diffusion. Thus, the material is forced to undergo a state transformation similar to that which occurs at a certain effective temperature. It has been reported that applied plastic deformation leads to phase transformation in the form of formation or decomposition of a supersaturated solid solution, dissolution of phases, disordering or ordered phases, and amorphous crystalline phases.^[15]

The goal of this study is to investigate the effect of different levels of plastic deformation on the hardening behavior of the AA2195 and to find the thermomechanical treatment, which produces an excellent hardness behavior combined with energy savings and cost-effectiveness. Moreover, the characterization of the different precipitates that dominate the microstructure of the AA2195 alloy has been developed. Since the composition evaluation of sub-nanometer-scale platelet precipitates is extremely difficult, atom probe tomography (APT) together with transmission electron microscopy (TEM) have been employed to characterize the local chemical composition of the precipitates and to determine the location of the various alloying atoms.

EXPERIMENTAL

Commercial aluminum alloy 2195 has been used as the primary material. The chemical composition of the alloy is presented in Table 1. The measured compositions using inductively coupled plasma optical emission spectrometry using an ICP-OEC 720-ES instrument is in good agreement with the nominal composition.

Samples of as-received material were machined into the shape of tensile samples. This shape is illustrated in Fig. 1. As shown in this figure, the sample has two sections: gage section and grip section. The specimens were first solution heat treated in a molten salt bath (75 wt.% KNO_3 , 20 wt.% NaNO_3 , and 5 wt.% NaNO_2) for 1 h at 520°C followed by ice water quenching. Then, they were

Fig. 1 Required geometry of tensile sample

stretched at different stretching levels: 0%, 1%, 2%, 3%, 4%, and 5%. The stretching was performed at a crosshead displacement of (1×10^{-4} m/min). The real-time elongation of each specimen was observed through a digital display via a computer interface with an extensometer across an initial gage. The non-stretched specimen (0%) and all stretched specimens (1%, 2%, 3%, 4% and 5%) were placed on quartz ampules that were sealed under vacuum. The specimens were then artificially aged in an electric furnace at 150°C for different times (0 (non-aging), 1, 10, 20, 30, and 40 h).

After the treatment, all specimens were tested by the Vickers microhardness test. The preparation of the specimens for the hardness test was accomplished by the standard metallurgy method (mechanically grinded by distilled water and SiC paper of 600, 1200, and 2400 grit sizes. This step is followed by final polishing to eliminate scratches by using colloidal silica on cloth). The aim of applying this metallographic method is to achieve a clean surface free from oxide particles, which allowed us to achieve the precise values of the hardness. The hardness tests were performed by using a load of 0.2 kg applied to the sample for 10 s. The hardness value was obtained by averaging 10 measurements.

Microstructural characterization at the atomic scale was performed using both TEM and APT. A TEM investigation was carried out by the utilization of FEI titan CT operated at 300 kV. The interaction of accelerated electrons within samples has been conducted under good vacuum conditions (10^{-5} Pa). The bright-field images were used to characterize the microstructure. Selected area diffraction patterns (SADP) were obtained for structural analysis on corresponding alloy phase identification present within the samples. Electron-transparent foils were grinded to an approximate thickness of 150 μ m, mechanically punched, and then electropolished by standard twin-jet polishing using a solution of 20 vol.% of nitric acid in methanol at -20°C. Atom probe studies were performed using a laser-assisted wide-angle tomographic atom probe (LAWATAP) in the voltage mode at 30 K with a pulse fraction of 20% and at a vacuum level of 10^{-8} Pa. Small rods ($0.3 \times 0.3 \times 10$ mm) were spark machined from the bulk and then electropolished to a sharp needle-shaped specimen for APT analysis. Electropolishing was performed using a solution of 30 vol.% of nitric acid in methanol at -20°C in the range of 5–7 V. The produced sample was in the shape of sharp needle-shaped specimen with an apex

radius between 50 and 100 nm. Examination of the quality of the prepared tip and the measurement of its dimensions are always performed by using scanning electron microscopy (SEM—Quanta 600). Moreover, the development of the tip's surface was examined by using field ion microscopy mode in LAWATAP. Based on this, an additional fine electropolishing step was not required.

The obtained APT data were visualized using the TAP3D and IVAS software programs provided by Cameca. Calibration of the main reconstruction parameters was performed by observing the atomic plane for the respective crystallographic pole. The composition of the different observed precipitates was measured quantitatively using the proximity histogram (proxigram) technique.^[16] In this methodology, an isoconcentration surface first delineated the precipitates. Next, starting at the isoconcentration surface, which is the origin of the proxigram, and then moving toward the center of precipitates (positive distance), the composition of the precipitate was measured according to discrete shells with the shape of isoconcentration surface at fixed intervals. The proxigrams in this study were selected with a spacing of 0.1 nm between these shells. The matrix composition was obtained by starting at the isoconcentration surface and moving into the matrix (negative distance). All obtained TEM images were recorded digitally and further treated using Gatan digital micrograph software.

RESULTS AND DISCUSSION

Characterization of an Al Alloy AA2195

TEM analysis of the specimen that has been stretched with 3% deformation level and artificially aged at 150°C for 30 h (similar to the heat treatment conditions of T8 temper) is shown in Fig. 2. In Fig. 2a, bright-field TEM image illustrates the nucleation of the platelet precipitates on both the grain boundaries and the matrix. This observation indicates that the grain boundaries act as the sinks of solute and vacancies that cause the precipitate to concentrate on its surroundings. A magnified view of one grain is shown in Fig. 2b. The image revealed a complex microstructure, including different precipitates with platelets and spherical morphology. Precipitates were characterized using an exact [110] zone. A schematic of the indexed SADP in the [101] direction in Fig. 2b indicates the presence of two variants of the T_1 precipitates as streaks along the $\langle 111 \rangle$ directions in the pattern. The other two variants of this phase produce spots adjacent to the $\langle 200 \rangle$ positions. The streaks along the $\langle 200 \rangle$ directions reveal the presence of the θ' precipitates. Because this phase lies on three orthogonal cube axes, the diffraction patterns manifest themselves as vertical and horizontal streaks.^[17] The super lattice reflection in the pattern is attributed to the β' precipitates. These observations provide evidence that the microstructure of

Fig. 2 Evolution of the microstructure as observed by TEM. (a) TEM bright-field image shows the nucleation of the T_1 platelet at the grain boundary and inside the grain. (b) Bright-field image of the microstructure inside the grain shows a complex microstructure with the T_1 , θ' and β' precipitates and the corresponding [101] SADP

stretched samples consists of the thin T_1 platelets associated with the smaller fraction of Cu-rich phase, i.e., θ' platelets and the β' phase.

Figure 3 shows the reconstructed volume of the sample that has been stretched with 3% deformation level and artificially aged at 150°C for 30 h (similar to the heat treatment conditions of T8 temper) analyzed by LAWATAP. In this analysis, the crystallographic direction perpendicular to the platelets precipitates has been aligned with the tip axis. To explain this idea, we need to discuss the texture of our respective material. Because most engineering materials are crystalline in nature, the microstructure can be considered the combination of morphology and orientation of the constituents. The morphology describes the shape of the constituents, whereas the orientation is connected to its crystallography. On this basis, the texture of a material is a constituent feature of a microstructure. In other words, texture can be defined as the arrangement of building blocks in polycrystalline materials.^[18] The texture in rolled sheet material is commonly represented by $\{hkl\}[uvw]$, which means that the $\{hkl\}$ planes of the specific grains lie parallel to the sheet plane, whereas their $[uvw]$ direction point is parallel to the rolling direction (RD). The sheet plane is usually perpendicular to the normal direction [ND], whereas its direction is parallel to the RD (Fig. 4). The major components of deformation texture in face centered cubic (FCC) materials (in Al alloy in our case) are $\{112\}\langle 111 \rangle$. Figure 4 illustrates that our respective material possess a strong rolling texture (sheet normal to $\{110\}$ planes, RD is $\langle 112 \rangle$). Thus, it is possible to prepare samples with a defined orientation, e.g., samples were prepared with their axis parallel to the $\langle 111 \rangle$ direction. This preparation has been accomplished by cutting the sheet sample

as illustrated in Fig. 5 in a direction parallel to $[112]$ by using a wire sewing machine and boron-carbohydrides as grinding particles. The sample was then rotated 90° to be aligned with $[111]$ direction. The final obtained product from this cutting procedure is a sample with a square shape and well-defined orientation. APT results for such preferentially oriented samples in Fig. 3 show the presence of sets of platelets. These platelets have been identified as T_1 and θ' phases according to their measured chemical compositions (Fig. 3b,c). The chemical composition of θ' platelets, as shown in the proxigram profile from 5 at.% Cu isoconcentration surfaces in Fig. 3b, is defined as (27 ± 3) at.% Cu, (2.30 ± 0.5) at.% Li, and (0.8 ± 0.5) at.% Mg, with the depletion of the Ag, while Fig. 3c is a proxigram profile from 4 at.% Cu isoconcentration surface of the T_1 platelet. The measured chemical composition for T_1 phase is (14 ± 2) at.% Cu, (14 ± 3) at.% Li, (4 ± 1) at.% Mg and (1.4 ± 0.4) at.% Ag. Results in Fig. 3 indicate the potential role of the development of texture on the strengthening mechanism.^[11] This role can be clearly seen in the interesting microstructure possessed by the rolled specimen with the uniform and homogeneous distribution of different platelet precipitates.

Engineering of an Al Alloy AA2195

Hardness Curves

The variations of hardness can reveal the precipitation process in the test material to some extent. Figure 6 shows the effects of stretching level and aging time on the hardness of AA2195 aluminum alloy. Figure 6a–f indicates that at the deformation levels of 0% (non-stretched),

Fig. 3 LAWATAP analysis for the specimen with rolling texture. (a) The presence of θ' and T_1 platelets in the reconstructed volume. (b) Proxigram composition profile for the θ' platelet. (c) Corresponding proxigram composition profile for the T_1 platelet

Fig. 4 Rolling texture of FCC material

1%, 2%, 3%, 4%, and 5%, the hardness values are somewhat high at the beginning (at 0 h aging time or non-aging), and then the hardness values decrease following by increasing to the peak hardness value. At the end of the curve, the hardness values decrease to relatively stable values. Table 2 shows the hardness values together with

Fig. 5 Cutting APT sample in the [112] direction and then rotating the sample to be in the [111] direction

their standard deviation values of AA2195 at different deformation levels.

The behavior of the hardness curves in Fig. 6 can be explained as follows: The hardness possessed by all

Fig. 6 Relationship between the aging time and the hardness values for AA2195 alloys aged at 150°C for (a) 0%, (b) 1%, (c) 2%, (d) 3%, (e) 4%, and (f) 5% stretching levels

specimens at all deformation levels at 0 h aging time (non-aging) is due to the applied plastic deformation, which leads to phase transformation. The phase transformation needs only a small shift of atoms (not a long mass transfer); hence, different phases from the respective equilibrium phase diagram can be formed and localized.^[15] Applying plastic deformation causes movement of the atoms induced by external forces; thus, both accelerated diffusion and phase transformation in the material would be achieved. One should note that the specimen at 0% deformation level (non-stretched) also has a good hardness response even without aging (150 HV at 0 h). In fact, this hardness behavior can be attributed to the presence of β' particles, which are formed during the solidification on the melt. The β' (Al₃Zr) phase is considered to be a hardening

phase in the quenched sample.^[19] It has been reported that β' particles do not undergo any further change during subsequent processing.^[20]

The decreasing hardness value at the next step in the curve is unexpected at first glance, considering the rapid aging response following the solution heat treatment. However, this can be explained by the annealing out of the quenched-in excess vacancies formed during the original aging. This action causes a long delay before a significant increase in hardness upon subsequent aging occurs.

The increasing of the hardness values to the peak hardness can be attributed to the formation of the second-phase particles, i.e., precipitates. As discussed before, applying plastic deformation causes the dislocation density and hence the overall number of nucleation sites to increase.

Table 2 Hardness values and the standard deviation of AA2195 at different deformation levels

Applied heat treatment conditions*	Hardness value (HV)
0% (non-stretched), aging 0 h	149.6 ± 6
0% (non-stretched), aging 1 h	114.8 ± 9
0% (non-stretched), aging 10 h	203.1 ± 19
0% (non-stretched), aging 20 h	168.4 ± 16
1% deformation level, aging 0 h	138.7 ± 5
1% deformation level, aging 1 h	108.2 ± 11
1% deformation level, aging 10 h	209.3 ± 3
1% deformation level, aging 20 h	135.3 ± 3
2% deformation level, aging 0 h	142.9 ± 6
2% deformation level, aging 1 h	114.5 ± 7
2% deformation level, aging 10 h	177 ± 8
2% deformation level, aging 20 h	143.6 ± 3
3% deformation level, aging 0 h	135.3 ± 5
3% deformation level, aging 1 h	127.7 ± 7
3% deformation level, aging 10 h	150.2 ± 8
3% deformation level, aging 20 h	209.3 ± 4
3% deformation level, aging 30 h	169.2 ± 5
3% deformation level, aging 40 h	140.3 ± 7
4% deformation level, aging 0 h	143.6 ± 7
4% deformation level, aging 1 h	123.8 ± 4
4% deformation level, aging 10 h	155.1 ± 3
4% deformation level, aging 20 h	215.5 ± 8
4% deformation level, aging 30 h	177.2 ± 1
4% deformation level, aging 40 h	184.4 ± 9
5% deformation level, aging 0 h	155 ± 3
5% deformation level, aging 1 h	142.9 ± 4
5% deformation level, aging 10 h	156 ± 4
5% deformation level, aging 20 h	160 ± 2
5% deformation level, aging 30 h	188.3 ± 2
5% deformation level, aging 40 h	171.6 ± 4

*All specimens aged at 150°C.

Thus, the incubation time required for nucleation will be shortened, and the formation of second-phase particles will occur. Note that at this stage, the times required to reach the peak hardness are different at different stretching levels: 10 h for the specimens at 0%, 1%, and 2% stretching levels; 20 h for the specimens at the 3% and 4% stretching levels; and 30 h for the specimen at the 5% stretching level. This shift of the time required to reach the peak hardness can be explained in terms of aging kinetics. The number of high-energy sites, dislocations, and vacancies increases as the deformation level increases. On this basis, the time required for the diffusion of solute atoms to fill the area of these sites will also increase as the deformation level increases. It seems that increasing the deformation level causes the saturated matrix to require more time

to nucleate or incorporate through a dislocation–particle interaction.

The final decrease of the hardness value to a relatively stable value is probably due to approaching equilibrium conditions, i.e., the loss of supersaturation. This is often considered to be the result of over-aging.

APT Analysis

Variation in the hardness values as a function of aging time at several levels of plastic deformation (Fig. 6) will be used as a guide to judge the optimal condition to engineer the commercial aluminum alloy AA2195. The beneficial effect of stretching prior to aging treatment on the hardness behavior is obvious. The non-stretched sample (0%) and the stretched samples with 1%, 3%, and 4% deformation levels prior to aging result in high hardness values (higher than 200 HV).

The criteria for selecting the best optimal thermomechanical conditions are low consumption energy and, hence, cost-effectiveness, in addition to the yielded superior mechanical properties. Although the non-stretched specimen (0%) has a good level of hardness, the thermomechanical condition that produces this specimen is not recommended as an optimal condition. This is simply due to the absence of applied plastic deformation, which leads to the absence of the uniform dispersion of second-phase particles. For the samples with 3% and 4% deformation levels, it is clear that the time required to reach the peak hardness is higher by 50% than that required in the case of the sample with 1% deformation level. This means that under conditions corresponding to 3% and 4% deformation levels, the consumption of energy will be high; thus, these conditions cannot be considered optimal. Note that stretching the samples by 3% prior to artificial aging is the procedure applied in industry (named as T8 temper)^[21] due to the softening behavior of the specimens under this condition (Fig. 6d). Examination of the hardness curve at 1% deformation level (Fig. 6b) shows that the high peak hardness value (209.3 HV) is reached after 10 h of artificial aging at 150°C. It is clear that under this condition, the consumption of energy for preparation is reduced (low deformation level, low aging temperature, and shorter time to reach the high hardness value). Thus, this condition is considered to be an optimal condition, which leads to generating a microstructure that achieves maximum hardness at minimum cost and energy consumption.

For intelligent microstructure design in the Al alloy, we need to gain a deep physical understanding of the correlation between the microstructure and macroscopic properties. On this basis, APT analysis was performed for the specimen, showing the high hardness value (i.e., peak age) at the 1% deformation level. Figure 7 shows the reconstructed volume of such a specimen. The top view of the reconstructed volume in Fig. 7a shows the presence of different T_1 platelets. Moreover, interesting cross

Fig. 7 LAWATAP analysis of sample at 1% deformation level (aged for 10 h at 150°C). (a) The top view of the reconstructed volume showing the nice distribution and dimension of the nano features. (b) Composition profile proxigram of the observed T_1 platelets

intersections of these platelets are shown. Some regions enriched with Cu and Ag also appear in the analysis. The chemical compositions of these precipitates, according to the proxigram profile based on the 1 at.% Li isoconcentration surface, are (10.2 ± 1.6) at.% Li, (9.9 ± 1.8) at.% Cu, (1.1 ± 0.5) at.% Mg, and (0.29 ± 0.16) at.% Ag (Fig. 7b).

From the APT analysis above, it is clear that introducing nanoscale second-phase particles in the Al matrix and a specific distribution of these particles lead to a huge improvement in the mechanical properties of the alloy. The specific distribution of precipitates with small thickness (between 1 and 2 nm) and closely spaced to each other (~ 9 nm) leads to approach an optimal situation corresponds to the high hardness value and hence a high level of strengthening especially by knowing that the maximum hardening is usually associated by the spacing between the precipitates particles equal to 10 nm.^[11] This optimal situation arises from the presence of the precipitate particles that are not small enough to be shared by dislocations and yet are too closely spaced to allow bypassing by dislocations. The increment of the aspect ratio (length to thickness ~ 20 – 22) causes the formation of a closed network of platelet precipitates that entraps gliding dislocation.

In conclusion, manipulation with second-phase precipitates in the microstructure is an important option to control the mechanical behavior of the complex Al alloy. Applying a plastic deformation prior to artificial aging has been highlighted as an important tool for this manipulation. Performing TEM and APT analyses for the specimens (with good hardening response) for all stretched levels will be the subject of the future analysis.

CONCLUSION

The standing goal of this study is to characterize and engineer a complex Al alloy AA2195 as an important structural material. Characterization of the alloy using high advanced techniques such as TEM and APT reveals that the microstructure of the alloy, after being stretched, consists of platelet-shaped T_1 (Al₂CuLi), θ' (Al₃Cu), and spherical β' (Al₃Zr) precipitates. Applying the rolling deformation on the specimen causes the uniform distribution of different platelet precipitates and hence indicates the potential role of the development of texture on the strengthening mechanism.

Engineering of AA2195 has been performed in order to have a balance among combinations of the high hardness value and low-energy consumption preparation method. The proposed strategy is divided into two parts. The first part is the mechanical strategy in which the mechanical characteristics of the alloy, such as its hardening ability, were employed to test the material. The second part of the proposed strategy is based on the idea of intelligent microstructural design. In this study, the effect of different levels of plastic deformation on the hardening behavior of the AA2195 has been investigated in order to find the thermomechanical treatment, which produces an excellent hardness behavior combined with energy savings and cost-effectiveness. We demonstrate the ability to have a robust microstructure with superior mechanical properties (hardness value of 209 HV) by applying a low-energy consumption, cost-effective method, with a deformation level of 1%, an aging temperature of 150°C, and a shorter time to reach the high hardness value of ~ 10 h.

Abstract

Different approaches for modeling of precipitation in Al–Mg–Si alloys are reviewed. First of all, the importance of a precipitation modeling and its interrelations with other components in a process model are explained. Then the empirical, statistical, and physically based modeling, with each being a different modeling approach, are introduced. The Kampmann–Wagner numerical (KWN) model, which is a physically based finite difference method, is explained as a model that is able to capture simultaneous nucleation, growth, and coarsening reactions. The growth kinetics in the KWN model is based on the assumption of local equilibrium hypothesis, inferring that there is an immediate thermodynamic equilibrium as soon as two phases are in contact. This assumption implies the diffusion-controlled nature of the transformation. The other extreme approach is the assumption of interface-controlled growth, where the interface reaction (atom transport across the interface) controls the kinetics. In reality, neither of these scenarios can be absolutely true. A modified version of KWN model such that the growth can be treated with a mixed-mode nature (neither pure diffusion-controlled nor pure interface-controlled) is introduced. How the geometry of precipitates can be incorporated into the precipitation model is also explained.

Keywords: Al–Mg–Si alloys; KWN model; Mixed-mode growth; Precipitation; Precipitation model.

INTRODUCTION

Replacement of steel with aluminum alloys has lately become a big concern for many industries, including but not limited to automotive and aerospace industries, mostly aiming for lighter products with less fuel consumption and a more environmentally friendly performance.^[1] Having a good combination of corrosion resistance, formability, and relatively low density over strength ratio, medium-strength Al–Mg–Si alloys (known as 6xxx series) are now widely used in structural components in aerospace and automotive industries.^[2–7] Precipitation-hardenable 6xxx series alloys, containing Mg and Si, sometimes with added copper, show great potentials for structural, automotive, and aerospace applications. Precipitation hardening in these alloys takes place during aging treatment. Depending on the desired temper, application, and thermomechanical process, the aging treatment can be done at room temperature or at elevated temperatures; the former is known as natural aging

and the latter is artificial aging. In some grades, a separate solutionizing treatment before aging is needed, whereas some alloys can be aged without a solutionizing treatment. Commercially available 6xxx grades are balanced in Si and Mg contents, or they have some excess Mg and Si. In order to achieve the maximum strength at T6 temper, 6xxx series alloys are usually aged at a temperature range of 150°C–220°C. The aging treatment is accompanied with a series of complex precipitation reactions, in which a series of metastable and stable precipitates with different chemistries and morphologies form and transform to each other. Formation and transformation of different precipitates is due to the simultaneous nucleation, growth, and coarsening. There have been many attempts to modify the chemistry of the 6xxx series alloys as well as the processing routes to produce alloys of improved properties for different applications. An example is the development and application of alloys AA6111 and EN-6016. The former alloy is largely used in the United States for

Fig. 1 Audi A8 is a great example of using aluminum in automotive industries

Source: www.totalmateria.com/page.aspx?ID=CheckArticle&site=ktn&LN=TR&NM=137.

outer panels due to its combined high strength with its superior formability. In Europe, however, EN-6016 is a more preferred choice. While the former shows more bake-hardened strength, the latter is known to be more resistant to corrosion.^[7] When it comes to the applications of 6xxx alloys in the automotive industry, perhaps one of the most exciting and revolutionary examples is related to the joint project between Alcoa and Audi, with the former being the supplier of aluminum sheets and the latter being the car producer. The cooperation between these two resulted in a space-frame design approach with >35% lighter body frame.^[1] The body of Audi A8, shown in Fig. 1, is almost completely made of aluminum. According to Audi, the use of aluminum instead of steel in some models can save up to some 130 pounds from the overall weight and results in a significantly less fuel consumption up to almost 20% (in A6 model). With current governmental and environmental demands, it is expected that proportion of Al-Mg-Si alloys in passenger cars will keep growing. There is always a tendency in the automotive industry to decrease paint-bake temperatures, which necessitates using alloys with faster kinetics of age hardening. There is no need to mention that any modification that scarifies formability will not be easily accepted in this industry.

Knowing all these complications about alloy chemistries and processing parameters and different needs from different industries, one can easily come to the point that optimization of chemistries and tuning mechanical properties of Al-Mg-Si alloys cannot be done without having a proper understanding of correlation between precipitation reactions, processing, and properties. This can obviously be achieved by developing precipitation models. A precipitation model can be seen as a link between process parameters (aging temperature, aging time, and thermo-mechanical history of the alloy), the chemistry of the alloy, and the grain structure on the one hand and the precipitate state of the alloy (precipitate size distribution, precipitate number density, and precipitate volume fraction) on the other hand. Precipitation modeling in Al-Mg-Si alloys is a very useful predictive tool to correlate processing parameters and alloy chemistry to the mechanical properties. The outputs of a precipitation model are needed as inputs in other models, including strength model, welding model,

Fig. 2 Schematic diagram of how different components of a process model correlate

and fracture model.^[8] Figure 2 shows a schematic of the interrelations between different components of a process model. One can see how important the role of a precipitation model is, when it comes to correlating the alloy chemistry and processing parameters to mechanical properties. Precipitation modeling can then be of critical importance when it comes to the development of alloys with modified chemistries and modification of routine processing routes. Using a predictive precipitation modeling gives relevant industries flexibility in such a way that they can deliver new products within a short time-to-market period.

This article aims at introducing precipitation modeling in Al-Mg-Si alloys. Different approaches will be explained and discussed. The Kampmann-Wagner numerical (KWN) model, which is a physically based finite difference framework, capable of capturing simultaneous nucleation, growth, and coarsening reactions, is briefly explained. How geometry and growth nature can be incorporated in the original KWN model is also addressed in this article.

PRECIPITATION MODELING APPROACHES

First of all, it is important to mention that the focus of this article is on the sharp interface approach, i.e., precipitates are assumed to be separated from the matrix with a sharp

boundary (the thickness of the boundary is infinitely small). On the contrary, the diffuse interface model assumes that the transition from one phase to another is continuous. The latter is mostly used in phase-field modeling, which is not the scope of this article. A range of different modeling approaches are used for different systems and applications. Grong et al.^[9] classified the modeling approaches into four categories: (i) empirical methods, (ii) statistical methods, (iii) physically based variable methods, and (iv) direct simulation of structure evolutions. The latter approach is mostly applied in the modeling of features, larger than grain size (i.e., modeling of grain growth during recrystallization). Obviously, since this approach is not appropriate for precipitation, it will not be covered in this article. The other three modeling approaches are summarized in “Empirical Methods”, “Statistical Methods”, and “Physically Based Methods” sections.

Empirical Methods

These models are known to be more descriptive than being really predictive. The basis of an empirical approach is to capture a specific behavior of materials by using pragmatic and simple equations. A classic example of this type of modeling is continuous cooling transformation diagram, which predicts the phase transformation during continuous cooling. The Johnson–Mehl–Avrami–Kolmogorov (JMAK) theory is also typically a widely used empirical method. The JMAK is only applicable to the overall progress of phase transformation during the growth period. When coarsening reaction becomes dominant, JMAK is not applicable anymore. The usefulness of this simple approach for modeling isothermal and non-isothermal aging treatments of Al–Mg–Si alloys has been discussed.^[10–13] In the JMAK approach, the evolution of the volume fraction of precipitates is obtained from the following equation:

$$f_r = 1 - \exp(-kt^n), \quad (1)$$

where f_r is the relative volume fraction of precipitates, t is the aging time, and k and n are two constants related to the material and process parameters, respectively. We showed in our previous work^[10] that discretizing this equation, one can model precipitation evolution during non-isothermal aging as well. The discretized form of the JMAK equation can be written as follows:

$$f_r = 1 - \exp\left(-\left[\int_0^{t_1} f(T_1)t^B + \int_{t_1}^{t_2} f(T_2)t^B + \dots + \int_{t_{n-1}}^m f(T_n)t^B\right]\right), \quad (2)$$

with B being a constant and T the temperature. Even though JMAK is a very simple and practical approach, it cannot be used when we are in the competitive coarsening regime. Also it is not possible to see where nucleation is dominant and where growth is playing a more important role.

Statistical Methods

The extensive experimental data, available in some areas, can be used as a good basis for application of statistical methods such as artificial neural networks and genetic algorithm for modeling different microstructural features and properties.^[14–20] One of the most important advantages of these statistical methods is their capability to capture complicated nonlinear interrelations between a large numbers of variables. However, the downside is that the success of these methods is heavily dependent on the availability of extensive experimental data. In another word, in case the data for setting up the model are not enough, the results can be misleading. Also, since these models have absolutely no physical foundation, many physical metallurgists prefer not to use them.

Physically Based Methods

In this category, models are closely related to and are essentially based on physical metallurgy. These models comprise two main parts, thermodynamic and kinetics parts, with the former providing information about local equilibrium and the latter predicting the kinetics of moving boundaries. Classical theories of nucleation, the influence of interfacial energy on the kinetics of growth, and the effects of curvature on the phase transformation in the coarsening regime are all important underlying physical facts that appear in physically based models in a way or another. Another important characteristic of these models is the role of microstructure as an input. One of the first attempts, and still one of the most successful precipitation modeling in Al–Mg–Si alloys, is a model introduced by Shercliff and Ashby.^[21,22] Even though this model is a success in modeling the kinetics of precipitation, it is not really based on the assumption of nucleation, growth, and coarsening, taking place simultaneously. One of the most realistic and possibly the closest models to the physics of precipitation is the KWN approach,^[23] which is explained in detail in “KWN MODEL” section.

KWN MODEL

The KWN model is a finite difference approach, which has the advantage of treating nucleation, growth, and coarsening in a natural way.^[23–27] This model keeps track of the flux of precipitates in and out of defined size classes at defined time steps during precipitation. The KWN modeling framework consists of the following three components: (i) nucleation model, (ii) growth/dissolution law, and (iii) continuity equation, which are briefly explained in Table 1. Figure 3 shows the flowchart of the KWN model, and Table 2 gives some typical values for input data used in the KWN model.

Table 1 Summary of the components of the KWN model

Components of the KWN model	Description
Nucleation model	$j = j_0 \exp \left(-\frac{Q_d}{RT} \left(\frac{1}{[\ln(C_m/C_e)]^2 \times (2(Q_s/RT)[\ln(C_0/C_e)]^{-3} + 3[\ln(C_0/C_e)]^{-2}} \right) \right)$ j_0: Pre-exponential constant, Q_d: activation energy of diffusion, C_m: mean solute concentration, C_e: equilibrium concentration, C_0: initial concentration, C_p: concentration of solute in the precipitate, Q_s: free energy of precipitate dissolution, T_s: solvus temperature
Growth model	$v = \frac{dr}{dt} = \frac{C_m - C_e}{C_p - C_e} \frac{D}{r}$ v: Growth/dissolution rate of precipitates, r: radius of precipitate, D: diffusion coefficient of solute
Continuity (mass balance) model	$\frac{\partial N(r,t)}{\partial t} = -\frac{\partial(N(r,t)v)}{\partial r} + \delta \left(r - \frac{2\gamma V_m}{RT} \left(\ln \left(\frac{C_m}{C_e} \right) \right)^{-1} \right) j(t)$ $N(r,t)$: Number density distribution function of precipitates of radius r, γ: interfacial energy, V_m: molar volume of precipitate, δ: number of precipitates in each time interval

Source: More details about the input parameters can be found in.^[25]

**Fig. 3** Flowchart of the KWN model

Choosing the alloying element that controls the diffusion has a big influence on the results. In case of Al–Mg–Si alloys, since the diffusivity of Si and Mg is almost similar,

it is possible to choose either of them. Also, even though the stoichiometry of precipitates changes during aging, it is common to assume single stoichiometry throughout the aging.^[24,25] More details about how parameters can be chosen can be found in the work of Bahrami.^[26] More comprehensive explanations and interpretations of results are also given in the mentioned reference. As an example of the outputs of the KWN model, the evolution of the size distribution of precipitates in the alloy AA6061, aged at 185°C, is shown in Fig. 4. It is seen that after 3 min of aging, the mean radius of precipitates is roughly 2 nm. By increasing the aging time, a broadening is seen in the size distribution curve, indicating that smaller precipitates have dissolved and bigger ones have grown. The model (at least qualitatively) predicts the observed log-normal size distribution of precipitates.

The KWN model can essentially be used in different aging treatments. Du et al.^[27] used a modified version of the KWN model, derived from the variational principle used in phase field method, for multicomponent conditions. Du et al.^[28] in another work predicted the kinetics of overaging in Al–Mg–Si alloys by using a coupled calculation of phase diagrams (CALPHAD)-KWN model. In their proposed framework, they managed to

Table 2 Summary of typical input data used in the KWN model

Input parameter	Value	Input parameter	Value
C_p (wt%)	63.0	γ (J/m ²)	0.26
D_0 (m ² /s)	2.2×10^{-4}	A_0 (kJ/mol)	16
Q_d (kJ/mol)	130	j_0 (#/m ³ s)	3.07×10^{36}
Q_s (kJ/mol)	45.35	V_m (m ³ /mol)	7.62×10^{-5}

Source: More details about the components of the model and equations can be found in.^[25]

Fig. 4 The evolution of the size distribution of precipitates in the alloy AA6061, aged at 185°C:^[30] (a) 180 s; (b) 3600 s; (c) 18,000 s; (d) 36,400 s

handle the coexistence of several different precipitate species, each having its own stoichiometry. In case precipitation kinetics of a mix of various precipitate is a concern, this approach can be very helpful. It has also been proved that the KWN model has its value in predicting the as-cast grain size of inoculated multicomponent aluminum alloys.^[29] In another case, in one of our previous works,^[4] the KWN model was used to see the effects of interruption during aging on the precipitation behavior of Al–Mg–Si alloys. The alloy used for this study was 1-mm-thick AA6061 (Al–0.95wt%Mg–0.62wt%Si–0.2wt%Cu) sheet delivered in T4 condition. The samples were solution heat treated in an air furnace for 20 min at 560°C, water quenched, underaged at 191°C for 15 min, kept at room temperature and 85°C for 7 days, and then re-aged at the same temperatures of underaging for various times. Figure 5 shows a schematic view of interrupted aging treatment.

Figure 6 depicts that when the interruption (the second stage of aging) is at room temperature, almost all secondary precipitates dissolve at the beginning of reheating. In this case, most precipitates have sizes below the critical radius of stable precipitates, and therefore, the dissolution is the governing reaction. However, when the interruption temperature is 85°C, most secondary precipitates are larger than 3 nm, and obviously, the precipitate growth becomes

Fig. 5 Schematic view of interrupted aging

the dominant reaction. This was shown to be the reason why high-temperature secondary precipitation has a significantly more positive contribution to the mechanical properties than the low-temperature one^[4]

MODIFIED KWN MODEL, CONSIDERING GROWTH CHARACTER

The KWN model is based on the assumption of diffusion-controlled growth. However, one can expect that the interface reaction (atom transport across the interface) can also play a role in the kinetics of precipitation. In reality, both diffusion and interface reactions have their own contributions in controlling the kinetics. This

Fig. 6 Influence of re-aging at 191°C on the evolution of the volume fraction of secondary precipitates, formed during 1-week interruption at (a) room temperature and (b) 85°C

mixed-mode character was implemented in the KWN model in one of our previous works.^[30] In order to make the growth nature a mixed-mode one, the parameter η is introduced as follows:

$$\eta = \frac{C_i - C_e}{C_m - C_i} \quad (3)$$

where C_i is the concentration at the interface, C_e is the equilibrium concentration, and C_m is the matrix concentration. When $C_i \rightarrow C_m$, $\eta \rightarrow \infty$, inferring that the solute diffusion is extremely fast. Eq. 3 yields $\eta = 0$ for $C_i = C_e$, meaning that the interface reaction is extremely fast. One can conclude that for $\eta \rightarrow 0$, the precipitation is diffusion controlled, whereas for $\eta \rightarrow \infty$, it becomes interface controlled. It is shown that when η -value is between 0.1 and 10, the precipitation reaction has the mixed-mode character. By increasing the aging time, the character of precipitation has a tendency toward diffusion control. In fact, with increasing aging time, precipitates become bigger, and therefore, larger amounts of solutes are needed to increase the mean radius of particles. In this case, solutes need to come toward precipitates

Fig. 7 The map of precipitation characters, assuming $Q_d = 130$ kJ/mol, with Q_d being the activation energy for diffusion

from far distances, making the growth character more diffusion controlled. In our previous work, we showed that the interfacial energy has a negligible influence on the growth character. On the contrary, diffusivity and mobility have more pronounced contributions to the precipitation character.^[30] The modified growth equation, considering the mixed-mode growth character, is given as follows:

$$\frac{dr}{dt} = bA_{ac} \exp\left(\frac{-\Delta G_a}{RT}\right) \left(\frac{\eta}{1+\eta}\right) \left(\frac{C_m - C_e}{C_e}\right), \quad (4)$$

where b is the interatomic distance, G is the Gibbs free energy, R is the universal gas constant, η is the growth character, and parameter A_{ac} is the accommodation factor. Figure 7 shows the relation between A_{ac} , the precipitate mean radius, and the growth character, for $Q_d = 130$ kJ/mol, with Q_d being the activation energy of diffusion. One can see that precipitates smaller than 2 nm are expected to grow in the interface-controlled mode ($\eta > 10$), whereas those being between 2 and 4 nm grow under mixed-mode condition. Precipitates larger than 4 nm can have either diffusion- or mixed-mode character.

MODIFIED PRECIPITATION MODEL, CONSIDERING THE MORPHOLOGY OF PRECIPITATES

In the currently available precipitation models, it is commonly assumed that precipitates have a spherical morphology. Nevertheless, β'' and β' phases are elongated needlelike and rodlike precipitates, both oriented in $\langle 001 \rangle$ Al directions.^[31] How this cylindrical morphology can be taken into the precipitation model is addressed in one of our previous works.^[32] In this model, all precipitates are assumed to be cylindrical with a constant aspect ratio. It is also assumed

Fig. 8 Prediction of the length of precipitate in the alloy AA6061 aged at 190°C

Source: Experimental data from Liu et al.^[33]

that precipitates have a constant aspect ratio during aging, and the interfacial energy at the tip and the rim of precipitates are taken equally. The thickening and lengthening (half-length: h) of a cylindrical precipitate can be obtained from the following equations:^[33]

$$h = \frac{2}{3} \left(\frac{C_m - C_e}{C_p - C_e} \right)^{1/2} \left(\frac{DA}{\pi} t \right)^{1/2} \quad (5)$$

$$r = \frac{2}{3} \left(\frac{C_m - C_e}{C_p - C_e} \right)^{1/2} \left(\frac{D}{\pi A} t \right)^{1/2} \quad (6)$$

where t is the time, D is the diffusion coefficient, and A is the accommodation factor. The developed model was applied to predict the mean length of precipitates during isothermal aging of the alloy AA6061 (1.12 wt% Mg, 0.57 wt% Si, 0.25 wt% Cu), aged at 190°C. Figure 8 shows the predictions of the model.

CONCLUDING REMARKS

Several precipitation modeling approaches, including empirical, statistical, and physically based KWN modeling, are introduced in this article. The latter approach is the one in which the precipitation nature is incorporated into the model. The KWN model is essentially a finite difference-based framework that is capable of capturing concurrent nucleation, growth, and coarsening reactions during aging. Interestingly, this happens naturally based on the amounts of solute left in the matrix, and one does not need to put any criterion (a critical size for instance) to shift from nucleation to growth and growth to coarsening. The traditional KWN is based on the assumption of diffusion-controlled growth. However, in reality, the interface reaction is not an infinitely fast reaction, meaning that the kinetics is controlled by both the matrix diffusion and the interface reaction. This approach is the basis of the

mixed-mode precipitation modeling, which is introduced in this article. In addition, given that metastable β'' and β' precipitates are not spherical, how the cylindrical morphology of precipitates can be taken into consideration is addressed in this article. There is still room for improvements in precipitation modeling of Al–Mg–Si alloys. One of the most important issues is the interfacial energy. This term can have tremendous influence on the kinetics of aging and the outcome of the model. So far, most models deal with this parameter as a constant parameter. Obviously, since the interface constantly changes during aging, this assumption needs to be improved in future versions of the KWN model. The same goes to the aspect ratio and accommodation factors. Also, future models need to be capable of re-producing precipitation sequence. A more realistic model is the one that predicts the moment when each species is transformed to another one in a natural way. Given that the precipitation sequence in Al–Mg–Si alloys is very complicated and there is not much available quantitative information about the way the interfacial energy, the aspect ratio, and the thermodynamic nature of precipitates change during aging, this will be very challenging.

Production Levels of Bauxite and Aluminum: Global Historical Survey (1850–2015)

Charles Christopher Sorrell and Pramod Koshy

School of Materials Science and Engineering, UNSW Sydney, Sydney, NSW 2052, Australia

Abstract

The present work provides a concise examination of the historical global production levels of bauxite, primary aluminum, and secondary aluminum from 1850 to 2015. It also provides a contextual background to these data by summarizing the main etymological, technical, and commercial developments throughout most of this period. It further includes comprehensive data for the pricing of primary aluminum in both historical and 2015 dollars on the basis of economy cost. The syntheses of the data include the following:

- Global production levels of bauxite based on three data sets
- Global production levels of primary aluminum based on three data sets
- Global production levels of secondary aluminum based on three data sets
- Comparative global production levels of secondary aluminum based on five data sets
- Prices of primary aluminum in historical US dollars and in US dollars indexed to 2015 values based on four data sets
- Conversion rates for historical US dollars against 2015 values

In addition to the preceding global data, extensive pre-1900 data for French, Swiss, and US production levels and French and US prices of primary aluminum are compiled.

Keywords: Bauxite; Historical pricing statistics; Historical production statistics; Primary aluminum; Secondary aluminum.

OVERVIEW

Although aluminum is the most abundant metal in the earth's crust,^[1] it does not occur as a native element owing to the low Gibbs standard free energy of formation of its oxide alumina (Al_2O_3), which precludes reduction by simple means.^[2] It is considered a *young* metal since its commercial production commenced at a relatively late date.^[3] Alum ($\text{K}_2\text{SO}_4 \cdot \text{Al}_2[\text{SO}_4]_3 \cdot 24\text{H}_2\text{O}$), which contains aluminum as a component, has been known since antiquity, being used in textile dying, in leather tanning, and as an astringent for blood coagulation.^[1] Although Wöhler led the ranks in the commercialization of aluminum by 1850,^[4,5] the first large-scale industrial process to produce aluminum was the chemical reduction route developed by Sainte-Claire Deville in 1854.^[1,2,4–12] The development of electrolytic reduction by the Hall–Héroult process in 1886^[1,2,6–8,13] had made Deville's process obsolete by 1891.^[8,9] The economic feasibility of the Hall–Héroult process was facilitated by the developments by Bayer during 1887–1892, which culminated in the development of the

hydrometallurgical process for the recovery of $\text{Al}(\text{OH})_3$ from bauxite.^[9,10,14,15] By this time, production levels were increasing rapidly and prices of aluminum were dropping equally rapidly, which enabled aluminum to establish itself in the marketplace as the first light metal available at large production levels. By 1960, aluminum had overtaken copper as the metal with the second largest global output, following iron.^[11,12,16] Today, while aluminum has multifarious uses, its major applications are in vehicles (28%), packaging (23%), and structures (14%).^[4]

TECHNOLOGICAL TIMELINE

An extensive summary of the most important events in the etymology, technical development, and commercialization of bauxite and aluminum has been prepared. The key technological developments have been referenced by the original publications or patents, which have required some revisions to commonly quoted dates and other misconceptions.

- 1658** Proposal that alum is an earthy material in post-humous publication by Swiss physician Paracelsus (1493–1541)^[17]
- 1684** Discovery that alum forms from the reaction of clay with sulfuric acid by the German physician Michael Ettmüller (1644–1683) in Leipzig^[18–20]
- 1722** Experimentation leading to the conclusion that alum contains an earthy component by German physician Friedrich Hoffman (1660–1742) in Halle^[7,21]
- 1728** Confirmation that alum contains an earthy component by French chemist Claude-Joseph Geoffroy le Cadet (1685–1752) in Paris^[22,23]
- 1754** Proposal that Al_2O_3 occurs in combination with SiO_2 in clays by German chemist Andreas Sigismund Marggraf (1709–1782) in Berlin, suggesting the term *argil* (from the Greek *árgillos* and the Latin *argilla*, meaning *white clay*) for clay^[1,20,23–26]
- 1782** Preparation of Al_2O_3 by heating of alum by French chemist Louis-Bernard Guyton le Morveau (1737–1816) in Dijon, suggesting the term *alumine* for the metallic component of the oxide^[2,8,23,27,28]
- 1789** Suggestion of the existence of elemental aluminum, albeit not separable from oxygen, by Antoine-Laurent de Lavoisier (1743–1794) in Paris^[19,20,25,28,29]
- 1803** Popular proposal (posthumous) of the term *alumina* for Al_2O_3 by Scottish chemist James Black (1728–1799)^[28,30]
- 1808** Preparation of impure aluminum (alloyed with iron) by electrolytic reduction of Al_2O_3 by mercury-potassium amalgam by English chemist Humphry Davy (1778–1829) in London, proposing the term *aluminum* for the metal^[31]
- 1812** Proposal of the term *aluminum* by Davy^[32]
- 1812** Proposal of the term *aluminium* by English polymath Thomas Young (1773–1829)^[33]
- 1821** Discovery of bauxite (*alumine hydratée*) by French geologist Pierre Berthier (1782–1861) near Les Baux-de-Provence (near Avignon)^[2,6,9,10,34,35]
- 1825** Isolation of relatively pure aluminum by chlorination of clay and carbon, followed by reduction of resultant AlCl_3 by mercury-potassium amalgam by Danish physicist Hans Christian Ørsted (1777–1851) in Copenhagen^[1,2,4–7,9,19,20,26,36]
- 1827** Fabrication of small particles of pure aluminum by reduction of AlCl_3 by potassium by German chemist Friedrich Wöhler (1800–1882) in Berlin^[1,2,4–8,26,37]
- 1845** Fabrication of globules of pure aluminum the size of pinheads, sufficient for determination of physical properties, by reduction of AlCl_3 by potassium by Wöhler in Göttingen^[5,7–9,38]
- 1847** Proposal of term *beauxite* by French geologist Ours-Pierre-Armand Petit-Dufrénoy (1792–1857)^{[9,35,39]a}
- 1850** Commercialization of aluminum by Wöhler^[5] or by Wöhler and German chemist Robert Wilhelm Eberhard Bunsen (1811–1899) in Heidelberg,^[4] with production, which may have commenced earlier and lasted at least until 1852, in Berlin
- 1852** Preparation of pure aluminum by electrolysis of AlCl_3 by Bunsen in Heidelberg^{[4,6,8,26,40]b}
- 1854** Improvement of the Wöhler chemical reduction process by subsequent addition of NaCl and heating to yield larger globules of aluminum by French chemist Henri Étienne Sainte-Claire Deville (1818–1881) in Paris^[1,2,4–9,26,41]
- 1854** Improvement of the Bunsen electrolytic reduction process by preparation of pure aluminum by electrolysis of AlCl_3 and NaCl by Sainte-Claire Deville^{[1,2,4–9,26,42]b}
- 1854** Preparation of Al_2O_3 from cryolite by Danish chemist Hans Peter Jørgen Julius Thomsen (1826–1909) in Copenhagen,^[9,11,12,36] published subsequently^[45]
- 1854** Commencement of cryolite mining at Ivigtut (now Ivittuut), Greenland by the *Den Kongelige Grønlandske Handel* (Royal Greenland Trading Company)^[46,47]
- 1855** First major publications providing detailed descriptions of fabrication and properties of aluminum by Sainte-Claire Deville^[48,49]
- 1855** Exhibition of cast pure aluminum at the *Exposition Universelle de Paris*^[9,26,50,51]
- 1855** Suggestion of cryolite as potential source of aluminum by English metallurgist John Percy (1817–1889) in London,^[5,11] apparently as personal communications to German mineralogist Heinrich Rose (1795–1864) in Berlin^[40] and Scottish metallurgist Allan Brugh Dick (1833–1926) in London^[52]
- 1855** Preparation of aluminum from cryolite by reduction by sodium by Rose^[5,8,9,11,12,37,40] and by Dick^[9,12,47,53]
- 1856** Establishment of first successful manufacturing facilities for production of aluminum, which was by reduction of $\text{AlCl}_3 \cdot \text{NaCl}$ by sodium (with fluorite as flux/solvent), by Sainte-Claire Deville in Glacière and Javel (Paris)^[2,6–12]
- 1856** Establishment of manufacturing facility for reduction of cryolite by sodium in Amfreville-la-Mi-Voie (near Rouen) by former employees of Sainte-Claire Deville, brothers Charles Tissier (1832–1864) and Alexandre

beauxite. This occurred only upon the publication of the third and final volume (1847) of the text, in which the Table of Contents gave this term and referred to the second volume.

^bThe date of Bunsen's use of electrolysis to prepare aluminum often is given incorrectly as 1854. When Sainte-Claire Deville, in his announcement of his production of aluminum by electrolysis in 1854,^[42] failed to mention Bunsen's publication of 1852,^[40] Bunsen took issue,^[43] to which Sainte-Claire Deville replied,^[44] drawing attention to the different salts that were used by the two researchers.

^aAlthough Dufrénoy described the ore reported by Berthier^[34] in the second volume (1845) of his *Traité de Minéralogie*, he did not use the term

- Tissier (1835–1860), following unsuccessful attempt at manufacture in 1855^[6,19,20,25,54]
- 1857** Transfer of aluminum manufacturing facilities by Sainte-Claire Deville to Nanterre (Paris) and formation of company *Société Anonyme de l'Aluminium*^[2,4,7,9,12,19]
- 1857** Development of aluminum bronze, the first commercial aluminum alloy, by Percy, acknowledged subsequently^[55,56]
- 1857** Anodization of aluminum by German chemist Johann Heinrich Buff (1805–1878) in Gießen, Germany^[2,57]
- 1858** Development of process to recover $\text{Al}(\text{OH})_3$ from bauxite by heating with Na_2CO_3 by French chemist Louis Le Châtelier (1815–1873) in Paris^[6,7,9,10,58]
- 1858** Publication of first text devoted to aluminum by the Tissier brothers, *L'Aluminium et les Métaux Alcalins. Recherches Historiques et Techniques sur leurs Propriétés, leurs Procédés d'Extraction et leurs Usages* (pp. xi+211)^[59]
- 1859** Publication of *De l'Aluminium. Ses Propriétés, sa Fabrication et ses Applications*, by Sainte-Claire Deville (pp. ix+176)^[60]
- 1859** Formation of *Compagnie des Produits Chimiques d'Alais et de la Camargue*, thereby establishing aluminum manufacturing facility by Sainte-Claire Deville in Salindres (near Nîmes), amalgamating the Le Châtelier thermal route and the Sainte-Claire Deville reduction route by conversion of bauxite to $\text{AlCl}_3 \cdot \text{NaCl}$ and reduction by sodium, with cryolite as flux/solvent^[2,6,8,9,11,12,61,62]
- 1860** Commencement of bauxite mining at Auriol (near Aix-en-Provence)^[35,63]
- 1861** Proposal of term *bauxite* by Sainte-Claire Deville^[10,35,64]
- 1876** Establishment of first major manufacturing facility for production of aluminum in the US by sodium reduction of Al_2O_3 by German-American metallurgist Johann Wilhelm (William) Gottfried Frishmuth (1830–1893) in Philadelphia, PA^[4,7,8,65]
- 1884** Installation of cast aluminum cap for the Washington Monument by Frishmuth in Washington, D.C.^[4,7,8,65]
- 1885** Publication of first text in German devoted to aluminum by Stanislaus Mierziński (no information located), *Die Fabrikation des Aluminiums und der Alkalimetalle* (pp. viii+112)^[66]
- 1885** Fabrication of aluminum bronze by carbothermal reduction of alumina by American metallurgists and brothers Eugene Hutchinson Cowles (1855–1892) and Alfred Hutchinson Cowles (1858–1929) in Cleveland, OH^[6,8,16,19,20,25,26,67,68]
- 1886** April 23, French Patent: Fabrication of aluminum by electrolytic reduction of Al_2O_3 dissolved in cryolite by French metallurgist Paul Louis Toussaint Héroult (1863–1914) in Gentilly (Paris)^[2,5,6,13,19,20,26,69]
- 1886** July 9, US Patents: Fabrication of aluminum by electrolytic reduction of Al_2O_3 dissolved in cryolite by American chemist Charles Martin Hall (1863–1914) in Oberlin, OH^[2,5,8,19,20,26,70,71]
- 1887** Publication of first text in English devoted to aluminum by English-American metallurgist Joseph William Richards (1864–1921), *Aluminium: Its History, Occurrence, Properties, Metallurgy and Applications, Including its Alloys* (later editions published in 1890 and 1896) (pp. xx+346)^[25]
- 1887** Modification of the Le Châtelier thermal route to extract Al_2O_3 from bauxite in hot caustic soda, introducing the initial modification of seeding by $\text{Al}(\text{OH})_3$, by Austrian chemist Karl Josef Bayer (1847–1904) in Tentelev (near St. Petersburg)^[1,2,6,8,9,11,12,15,16,35,72,73]
- 1887** August 30: Establishment of aluminum manufacturing facility, *Schweizerische Metallurgische Gesellschaft / Société Métallurgique Suisse*, by Héroult in Neuhausen, Switzerland^[6,8,11,74]
- 1888** October 1: Establishment of aluminum manufacturing facility, *Pittsburgh Reduction Company* (subsequently *Alcoa*), by Hall in Pittsburgh, PA^[7,11,16,75]
- 1888** October 17: Establishment of aluminum manufacturing facility, *Société Electrometallurgique de Froges*, by Héroult in Froges (near Grenoble)^[6,11,16]
- 1888** November 12: Merger of *Allegemeine Elektrizitäts-Gesellschaft* and *Schweizerische Metallurgische Gesellschaft / Société Métallurgique Suisse* to form *Aluminium Industrie Aktiengesellschaft* (subsequently *Alusuisse SA*) by Héroult in Neuhausen^[6,8,16,74,76,77]
- 1889** More economical preparation of aluminum in large volumes by sodium reduction of bauxite by American industrial chemist Hamilton Young Castner (1858–1899) in New York, NY^[4,9,10,19,20,78,79]
- 1889** Development of cryolite as electrolyte for Al_2O_3 by German metallurgist Martin Kiliani (1858–1895) in Neuhausen^[6,9,11,19,20,67,80]
- 1891** Closure of last manufacturing facility using the Sainte-Claire Deville method of chemical reduction in Neuhausen^[8,9]
- 1891** Discovery of bauxite in Little Rock, AR by American geologist John Casper Branner (1850–1922) in Little Rock, AR^[81,82]
- 1892** Development of final modification of the Le Châtelier thermal route, which was pressure leaching, leading to full hydrometallurgical process for recovery of $\text{Al}(\text{OH})_3$, by Bayer in Tentelev^[1,9,11,12,15,72,83]
- 1892** Establishment of Al_2O_3 manufacturing by the Bayer process by *Société Française d'Alumine Pure* in Gardanne (near Aix-en-Provence)^[6,14,35,84]
- 1895** Establishment of first major bauxite mining company in France, *Société l'Union des Bauxites*^[63,85]
- 1898** Commencement of bauxite mining in Little Rock, AR^[86]
- 1902** Establishment of Al_2O_3 manufacturing by the Bayer process in St. Louis, MO^[14]

- 1904** Establishment of first known aluminum recycling facilities, which were in Chicago, IL and Cleveland, OH^[87]
- 1906** Development of first age-hardened aluminum alloy *Duralumin* by German metallurgist Alfred Wilm (1869–1937), who was working for *Centralstelle für Wissenschaftlich-Technische Untersuchung, G.m.b.H.* in Neubabelsberg (near Berlin),^[6,88–91] although initial alloys had been developed by 1903^[92,93]
- 1918** Development of self-baking anode for aluminum processing by the Hall–Héroult process by Swedish-Norwegian electrical engineer Carl Wilhelm Söderberg (1876–1955), who was working for *Det Norske Aktieselskab for Elektrokemisk Industri Norsk Industri-Hypotekbank*, in Oslo^[11,94–97]
- 1919** Development of aluminum-lithium alloys, named *sclerons*, by the *Metallbank und Metallurgische Gesellschaft Aktion Gessellschaft* in Frankfurt am Main^[89,98,99]
- 1920** Preparation of very high-purity aluminum (99.99 wt%) by electrolytic refining (*electrowinning*) by American electrical engineer William Hoopes (dates unknown) in Pittsburgh, PA^[16,100–105]
- 1921** Merger of *Société Electrometallurgique de Froges* and *Compagnie de Produits Chimiques d'Alais et de la Camargue* to form *Compagnie des Produits Chimiques d'Alais, Froges et Camargue* (subsequently *Péchiney*)^[6]
- 1927** Development of *Alclad*, a corrosion-resistant coating of pure aluminum (bonded to *Duralumin*), by Edgar H. Dix, Jr. (1892–1963) in Pittsburgh, PA^[106,107]

availability of online resources and the personal computer, summarizes national and global production levels of bauxite, primary aluminum, and secondary aluminum as well as historical prices for the metals up to the year 1976. When selected data for the earlier years are available from other sources and the trends harmonize, these individual statistics are used.

2. *US Geological Survey (USGS) Minerals Yearbook*. These annual reports represent an indispensable database for the years 1931 to present for bauxite and primary aluminum. Since these data usually are presented in 5-year annual groupings, the latest entry is used in all cases. All of these documents are available at the USGS website.^[109] Although not used, relevant data for 1913 to 1932 are available in graphical form in the inaugural edition of the *Minerals Yearbook* of the *US Bureau of Mines*. This document also is available online.^[110]

Other major data sets, which do not appear to be referenced directly by Schmitz^[108] as sources, are as follows:

3. *Metal Statistics*, which has provided global and commodity pricing data in 10-year annual groupings from its first annual edition in 1907. It was published initially by the *American Metal Market Company* (New York) but, since 1966, has been published by *Metallgesellschaft Aktiengesellschaft* (Frankfurt am Main). This information includes annual global production data for bauxite, primary aluminum, and secondary aluminum.
4. *British Geological Survey*, which has archived the relevant publications of its predecessors, covering the years from 1913. These data, which include annual global production data for bauxite and primary aluminum, are available online.^[111]
5. *World Metal Statistics* and *World Metal Statistics Year Book*, which are published monthly and annually, respectively. These publications, which commenced in 1967, include global production data for primary and secondary aluminum in 10-year groupings.
6. *International Aluminium Institute*, which has provided annual global production data in graphical form for primary and secondary aluminum, covering the years from 1950, since its founding in 1972.^[112]

There also is a compilation of data in 5-year intervals covering the years 1890 to 1990, which incorporates largely the data of Schmitz^[108] and later editions of *Metal Statistics*. This online resource of the *PBL Netherlands Environmental Assessment Agency*, which is its *History Database of the Global Environment*,^[113] includes global production data for bauxite, primary aluminum, and secondary aluminum. These data have not been used since they are not annual.

GENERAL COMMENTS CONCERNING DATA

Global Production Levels

It will be appreciated that historical data often are imprecise owing to the scarcity of accurate information on production levels, although even modern data may suffer the same shortcoming. In the present work, the formalism that has been adopted is, when the major data sets overlap and inevitably disagree, to accept contiguous data that report generally the highest production levels on the assumption that they represent the broadest coverage of the information available. The continuity of the different data sets was ensured by selecting successive years of similar production levels for both data sets (i.e., ending and commencing where the data sets cross).

The two most important sources of production data that have been used are as follows:

1. Christopher J. Schmitz, *World Non-Ferrous Metal Production and Prices, 1700–1976*.^[108] This remarkable collection of data, compiled prior to the

Global Pricing

Schmitz^[108] does not provide commodity pricing data for bauxite. The *USGS Minerals Yearbooks*^[109] also do not provide these data for bauxite but they do provide limited data for certain locales.

Historical commodity pricing data for primary aluminum are available from Schmitz^[108] up to 1976. Commodity pricing data for 1977 to present were obtained from the *USGS Minerals Yearbooks*^[109] using the annual average of the cash price of the London Metals Exchange.

Commodity pricing data for primary aluminum were determined using the online calculator *MeasuringWorth.com*^[114] in order to index the prices to 2015 US dollars. The basis for the calculations was the economy cost, which is assessed in terms of the relative share of economic output. It is calculated using the share of the gross domestic product and is the most inclusive method of calculation. The conversion rates used are shown in Fig. 1 and tabulated in Appendix 1.

There do not appear to be any databases that compile historical commodity pricing data for secondary aluminum. These data would be complicated by the separate statistics for new and old scrap as well as the different prices associated with the many varieties of scrap.

BAUXITE AND ALUMINUM PRODUCTION

Bauxite Data

Three principal data sets were synthesized to compile the global production data for bauxite, which are shown in Fig. 2 and tabulated in Appendix 2:

1860–1889	Régnier ^[35] Data in metric tons
1890–1930	Schmitz ^[108] Data in metric tons
1931–2015	<i>USGS Minerals Yearbooks</i> ^[109] Data in metric tons (1931–1934, 1975–2015) and long tons (1935–1974)

The main inflections in these curves correspond to major technological, wartime, or commercial events, which are indicated in Fig. 2.

Habashi^[10] has provided comprehensive data for 1860 to 1990 but the source of these data is not cited and they are in the form of a semilogarithmic plot that is at some variance with the data of the present work. Régnier,^[35] an employee of *Péchiney*, has provided both a linear plot and tabulated data at 10-year intervals for the years 1860 to 1910 and fairly comprehensive tabulated data for the years 1913 to 1950. The sources of these data also are unstated.

Primary Aluminum Data

Production

Three principal data sets were used to synthesize the global production data for primary aluminum, which are shown in Fig. 2 and tabulated in Appendix 3:

1859–1930	Schmitz ^[108] Data in metric tons
1931–2011	<i>USGS Minerals Yearbooks</i> ^[109] Data in metric tons (1931–1934, 1980–2015) and short tons (1935–1979)
2012–2015	Unpublished data transmitted by personal communication from E.L. Bray, <i>USGS</i> ^[117] Data in metric tons

Fig. 1 Historical conversion rates from historical US dollars to 2015 US dollars (on basis of economy cost)^[114]

Fig. 2 Historical global production levels of bauxite, primary aluminum, and secondary aluminum^[35,108,109,115–117]

Although all of the data sets agree relatively well, the data of Schmitz^[108] have been used for the years prior to 1931 because they are the most comprehensive in terms of the time span. The data of the *USGS Minerals Yearbooks*^[109] have been used when they overlap with those of Schmitz^[108] (viz., 1931–1976) and for subsequent years because, while they are in agreement for the early years, they diverge considerably after World War II, with higher production levels being cited by the former. The data for 2012–2015 are revised^[117] from preliminary data published by the *USGS*.^[109] The statistic for 1856^[10,19,20,118] is included in Fig. 2 and Appendix 3 because commercial primary aluminum production in 1856 appears to have been unique to the manufacturing facilities in Glacière and Javel; other early individual statistics are not included because they tend not to harmonize with the data sets used.

The early data for global primary aluminum production by Neumann,^[118] which include data for 1883 to 1900, were not used because the production levels are substantially lower than those given by Schmitz.^[108]

It remains generally unknown that the first commercialization of aluminum was by Wöhler, which had occurred by 1850^[4,5] and lasted at least until 1852,^[26,75] although Wöhler may have worked jointly with Bunsen.^[4] This production took place in Berlin, which is confirmed by the early chemical analysis of commercial aluminum produced in this city.^[26] This analysis was undertaken by the Irish chemist John William Mallet (1832–1912), who studied under Wöhler at the University of Göttingen during 1851–1852, receiving his Ph.D. in the latter year.^[119]

In 1854, Sainte-Claire Deville became the second to commence manufacture,^[1,2,4–9,26] although the Tissier brothers followed closely behind in 1855.^[54] However, theirs was not a commercial success and the venture folded early the following year. It appears that Sainte-Claire Deville's plants in Glacière and Javel in 1856 and Nanterre

in 1857 were the only significant producers of aluminum during these years.^[6,10,19,20] Le Roux^[6] and Régnier^[35] have commented that the production facility at Salindres was the only plant in the world to produce both aluminum and alumina regularly and commercially during 1860–1890. Habashi^[12] commented that the Salindres plant was the sole producer of aluminum from 1860 to 1885. However, Schmitz^[108] shows (or implies by trend when the data are absent) consistently higher global outputs than are recorded for these facilities.

The earliest individual French production data that have been located are given in Table 1.

While Wöhler was able to achieve a purity of 96.25 wt%,^[26] Sainte-Claire Deville obtained purities of 88.35–96.16 wt% in Glacière and Javel, 97.00–98.29 wt% in Nanterre, and 95.00–99.00 wt% in Salindres.^[19,20] The Tissier brothers in Rouen were able to achieve a purity of 94.80 wt%. No data for the purities obtained by Héroult in Froges have been located.

The earliest individual Swiss production data that have been located are given in Table 2.

Héroult was able to achieve purities of 94.15–95.00 wt%,^[20] and possibly as high as ~97–99 wt%^[26] initially in Neuhausen.

Other data not used in the present work include more contemporaneous data for US production published by Richards in 1896^[20] and Thorpe in 1912,^[26] which are given in Table 3.

While Frishmuth was able to produce aluminum purities of 97.49–97.75 wt%,^[19,20] Hall was able to guarantee a purity of 98.34 wt% by 1889,^[19] eventually achieving 99.93 wt% by 1896.^[20]

These data indicate that the assumption that production of primary aluminum during 1860–1885 or 1890 was limited to France is incorrect. This is made clear by Neumann's 1904 tabulation of French, Swiss, German, and English primary aluminum production levels during 1859–1900,^[118]

Table 1 Early French domestic production data for primary aluminum (some processes and locations deduced)

Year	Output (kg)	Process	Location	References	Year	Output (kg)	Process	Location	References

the numerous other manufacturers that are listed in Richards’ historical summaries of 1887–1896,^[19,20,25] and the compilation by Schmitz.^[108]

Pricing

Four principal data sets were used to synthesize the historical commodity pricing data in US dollars for primary aluminum, which are shown in Fig. 3 and tabulated in Appendix 4:

1852–1856 Smith^[75]
Original data provided by Alcoa in 1897 (for years 1852, 1854, 1855, 1856 [one price], and 1862)

1856–1878 Richards^[19,20]
Data published in 1890 and 1896 (for years 1856 [two prices], 1859, 1862, and 1878)
1879–1976 Schmitz^[108]
1977–2015 *USGS Minerals Yearbooks*^[109]
Data based on annual average of the London Metals Exchange cash price

Overlapping and complementary data given by Smith^[75] and Richards^[19,20] are used because they are consistent and the identical statistics for the years 1862 and 1886 (not used) suggest that they were drawn from the same sources. Although data for 1854 to 1894 are given by Schmitz,^[108] which are copied from Neumann,^[118] they are in marks (viz., the Hamburg mark banco [pre-Unification prior to 1871] and the German mark [following Unification in 1871]). However, both the mark and US dollar prices are given by Schmitz^[108] for 1895. Since, the online calculator *Historical Currency Converter (Test Version 1.0)*^[126] reveals that the exchange rate of the German mark vs US dollar did not change during 1878 to 1895, then the 1895 exchange rate from Schmitz^[108] was used to calculate the commodity pricing data for 1878. This was used as a confirmatory check for contiguous consistency between the data of Smith,^[75] Richards,^[19,20] and Schmitz.^[108] The data of Schmitz^[108] for the earlier years are not included because the calculator uses the labor value, which is based on the pay of workers and their purchasing power rather than the economy cost used by *MeasuringWorth.com*.^[114] Consequently, these two methods of calculation yield inconsistent data trends. The unused data of Schmitz^[108] and Neumann^[118] are given in Table 4.

The statistic for 1850, which is included in Fig. 3 and Appendix 4, is for aluminum produced by Wöhler. There are two disparate prices that have been quoted, these being US\$352.74 per kg (published in 1936)^[5] and US\$1,410.96

Fig. 3 Historical price of primary aluminum in historical US dollars per metric ton^[20,75,108,109]

Table 4 Early international commodity pricing data for primary aluminum

Year	Historical marks per kg	Conversion rate ^a	Historical US dollars per kg	References
1854	2,400	0.3705	889.20	[108,118]

1897	0.86	Hall	Niagara Falls	[127]
1897	0.79	Hall	Niagara Falls	[75]

^aImported price.

There are other early data for prices in UK pounds^[24] and US dollars^[4,5,12,19,20,25] but they have not been used.

Bray^[127] also has provided limited data for prices in the US that indicate that price parity with Europe tended to be the case, although there is significant disagreement with the other two prices cited for 1850.^[4,5] These and other unused data are given in Table 6.

The commodity pricing data for primary aluminum indexed to 2015 US dollars, calculated using the conversion rates shown in Fig. 1 and tabulated in Appendix 1, are shown in Fig. 4 and tabulated in Appendix 5.

These data and those of Fig. 3 suggest that stabilization of the price trend of primary aluminum (Point *I*) was initiated not by technical or economic factors associated with aluminum but from the large-scale availability of bauxite.

Secondary Aluminum Data

Three principal data sets were used to synthesize the global production data for secondary (recycled) aluminum, which are shown in Figs. 2 and 5 and tabulated in Appendix 6:

Fig. 4 Historical price of primary aluminum in 2015 US dollars per metric ton (on basis of economy cost)^[20,75,108,109,114]

1913–1945	Schmitz ^[108]	There are two other global production data sets, the latter of which generally remains unknown because it is in an obscure location in the <i>USGS Minerals Yearbooks</i> : ^[109]
1946–1976	Data in metric tons Unpublished data compiled by P.A. Plunkert, <i>USGS</i> , and transmitted by personal communication from E.L. Bray, <i>USGS</i> ^[115]	1975–2016 Data tabulation received by personal communication, <i>World Bureau of Mineral Statistics</i> , although published annually in <i>World Metal Statistics Year Book</i> ^[130]

	Data in metric tons	Data in metric tons

What appear to be the unpublished *USGS* data have been tabulated in approximated form in 2001^[128] and 2007.^[129]

The online data set of *PBL Netherlands Environmental Assessment Agency*, which is its *History Database of the*

Fig. 5 Historical global production levels of secondary aluminum^[108,115,116]

Fig. 6 Comparative data for global production levels of secondary aluminum^[108,109,115,116,130]

Global Environment^[113] and covers the years 1890–1990 in 5-year intervals, has been mentioned previously.

It can be seen that acquisition of comprehensive production data for secondary aluminum represents a challenge to the researcher. Since none of these data are readily obtainable and there are some variations, these are shown on a comparative basis in Fig. 6 and tabulated in Appendix 7.

A final point concerning the secondary aluminum data is that the proportion of recycled aluminum relative to the total amount of aluminum produced during the period 1950–2015 has increased only from ~13% to ~15%.

1914	Beginning of World War I
1918	End of World War I
1929	Onset of Great Depression
1939	Beginning of World War II
1945	End of World War II
1956	World aluminum overproduction ^[109]
1973	First oil shock
1980	World aluminum overproduction ^[109]
1984	World aluminum overproduction ^[109]
2007	Global financial crisis

Combined Global Production Data

The global production data for bauxite, primary aluminum, and secondary aluminum, which are shown together in Fig. 2, not surprisingly suggest that changes in the trends of production levels can be attributed principally to technological developments, wartime production requirements, and/or transient economic conditions. Hence, the major inflections representing alterations in the linked global bauxite, primary aluminum, and secondary aluminum production levels can be detected for the following major developments and events:

1850	Commercialization of aluminum by Wöhler ^[4,5,26,75,119,127]
1854	Introduction of the Sainte-Claire Deville process to produce aluminum by chemical reduction ^[1,2,4–9,26,42]
1860	Beginning of bauxite mining ^[35,63]
1886	Introduction of the Hall–Héroult process to produce aluminum by electrolytic reduction ^[2,5,6,13,19,20,26,69–71]
1887	Introduction of the Bayer process to produce alumina ^[1,2,6,8,9,11,12,15,16,35,72,73,83]
1907	Financial Panic of 1907

CONCLUSIONS

The present work has a dozen principal aims. *First*, it provides a comprehensive technological timeline that lists the relevant etymological, technical, and commercial developments as background for the global production data that follow. *Second*, the timeline provides detailed referencing, including citations of the original key technical publications or patents, which have allowed revisions of some misconceptions. *Third*, it establishes a comprehensive and contextualized database for global production levels of bauxite, primary aluminum, and secondary aluminum. The data for all three commodities have been plotted together in order to allow comparison. *Fourth*, it provides contextualized commodity pricing data for primary aluminum in historical US dollars. *Fifth*, these pricing data are made comparable by indexing them to 2015 US dollars on the basis of economy cost. The data compilations for both production and pricing are for the relevant years within the period 1850–2015 and the sources of all of these data are specified. *Sixth*, tabulations of early French, Swiss, and US domestic production levels have been compiled from a range of mostly early publications. *Seventh*, tabulations of early French and US domestic commodity pricing data also have been prepared. These two compilations of

pre-1900 production and pricing data are more comprehensive than available elsewhere. *Eighth*, while published and online data invariably are presented graphically, the compiled data are presented in both graphical and tabulated forms, the latter of which preclude the necessity of interpolation and approximation. These data synthesize multiple contiguous data sets in order to provide comprehensive data compilations for these three commodities. *Ninth*, the timeline is extended to include the years back to 1850. Data for global primary aluminum production pre-1900 do not appear to have been compiled and published previously outside of the book by Schmitz.^[108] While there are extensive data for global bauxite production by Habashi^[10] and Régnier,^[35] these are not referenced, although the latter data, which were prepared by an employee of *Péchiney*, have been used in the present work. *Tenth*, all of these data are present in a single literature resource. *Eleventh*, there is a master plot for global secondary aluminum production extending back to 1913. A complete set of these data does not appear to have been compiled previously. *Twelfth*, there is a comparative plot of differing data sets for global secondary aluminum production, most of which are not readily obtainable.

ACKNOWLEDGEMENTS

The authors wish to express their appreciation to Mr. E. Lee Bray, Mineral Commodity Specialist, *US Geological Survey*, for provision of unpublished global primary aluminum production data for 2012–2015, which are

revisions of those published originally in the *USGS Minerals Yearbooks*.

The authors also wish to express their appreciation to the following for their personal communications of global secondary aluminum production data:

Mr. E. Lee Bray—for provision of unpublished tabulated data compiled by Dr. Patricia A. Plunkert, *US Geological Survey*

International Aluminium Institute—for provision of tabulated data normally available only graphically online

World Bureau of Metal Statistics—for provision of tabulated data available only in *World Metal Statistics* and the *World Metal Statistics Year Books*

The authors further wish to thank the owner-operators of the websites that provide online currency conversions for their clarifications:

Mr. Samuel H. Williamson, *MeasuringWorth.com*
<https://www.measuringworth.com/uscompare/>
Assoc. Prof. Rodney Edvinsson, *Historical Currency Converter (Test Version 1.0)*

<http://www.historicalstatistics.org/Currencyconverter.html>

The authors also are grateful to Mr. Ole Andersson, retired, School of Materials Science and Engineering, UNSW Sydney, for his translation from the antiquated Danish, which allowed confirmation of the technology and pagination of the original publication by Ørsted.

Finally, the authors wish to express their appreciation for the sleuthing skills of Mr. Arnaud Bastide, visitor, and Ms. Luisa Schreck, undergraduate student, who helped to track down elusive patents.

Abstract

The production of Al from its ores at present relies on the Bayer (alumina production) and the Hall–Heroult (Al production) process. The cost associated with alumina production and apparent disadvantages of the Hall–Heroult process have led to intensive research to find alternative routes for Al production. The direct carbothermal reduction process has been thoroughly investigated as an alternative technique. Another alternative includes the indirect carbothermal reduction route where alumina (or aluminous ores) is first reduced to intermediate Al compounds before reduced further to Al. The present study reviews and provides systematic thermodynamic analyses of alternative Al production routes. In this paper, a comprehensive review of alternative Al production techniques focusing on the indirect carbothermal reduction routes is presented. These include carbochlorination, carbonitridation and carbosulphidation routes for the formation of intermediate Al compounds, followed by various Al extraction processes.

Keywords: Carbochlorination of alumina; Carbonitridation of alumina; Carbosulphidation of alumina; Carbothermal reduction of alumina; Disproportionation; Electrolysis; Thermal dissociation.

INTRODUCTION

Aluminium is the most abundant metallic element in the Earth's crust (~8%) and the second most widely used metal next to steel. The production of Al has increased by nearly four times in the last three decades (Mahadevan et al., 1996). Pure Al cannot be found in nature because of its high affinity to oxygen. In general, it is found in a variety of minerals combined with various elements such as silicon, oxygen, phosphates, fluorine and hydroxides. In the last century, a number of methods have been developed to extract Al from its ores. The current commercial production method relies on two energy intensive processes developed in the late 1800s: the Bayer process which produces pure alumina from bauxite ore, and the Hall–Heroult electrolysis process which produces Al metal from the alumina. The cost of the Bayer process represents ~27% of the cost of Al production^[54] and the Hall–Heroult process uses about three quarters of the total energy requirement, though these numbers vary depending on the specifics of the ores and sources of energy used.

The Bayer process is the principal industrial technique to refine bauxite to pure alumina. There have been little changes to the basic process since the first plant opened in 1893. In this process, bauxite (containing typically 10–30 wt-%Fe₂O₃, 4–8 wt-%SiO₂ and 2–5 wt-%TiO₂ as major impurities) is dried, ground, digested in sodium hydroxide under pressure.^[100] Impurities are separated by filtration, before alumina hydroxide is precipitated and calcined to produce commercial alumina. The relatively high purity alumina produced from the Bayer process is then transferred to the Hall–Heroult electrochemical cell for electrolysis.

The Hall–Heroult process was patented in 1886 and the basic process layout remains unchanged except for the form of the carbon anode (Brooks et al., 2007). There has been significant improvement in the process over last hundred years, through increasing cell size, greater automation and control, and improved control of emissions. Tarcy et al.^[119] provided an outline of the improvements in a recent review, showing that the overall energy usage per kg of metal has decreased from typically over 30 kWh kg⁻¹ Al in 1914 to below 14 kWh kg⁻¹ Al by 2000.

In the Hall–Heroult process, Al metal is extracted through electrolysis of Al_2O_3 dissolved in NaF–AlF_3 (cryolite) solution according to the following overall reactions:

In this process, liquid Al is produced at the bottom of the cell and CO and CO_2 gases are evolved from the bath. The Hall–Heroult process also generates greenhouse gases such as CF_4 and C_2F_6 from the carbon electrode and reactions with liquid cryolite (Na_3AlF_6). Per fluorocarbons (PFCs) may also forms during the so called anode effect when the electrolyte becomes depleted in alumina.^[92] In general, the process has high capital costs, low productivity compared to other metallurgical processes and consumes significant energy (from 12.9 to 15 kWh kg⁻¹ Al).^[53,87,116] The production of each kg of Al consumes between 0.4 and 0.5 kg carbon in the form of anodes and in total, Al production contributes to 2.5% of the world anthropogenic CO_2 equivalent emissions.^[44] This value will vary from plant to plant as it depends on energy source, the details of the cell and quality of the feed materials.^[118]

The apparent disadvantages of the Hall–Heroult process have led to numerous researches to develop alternative routes throughout the twentieth and early twenty-first centuries. The most important alternatives that have been envisaged include modified Hall–Heroult process utilising inert anodes, direct carbothermal reduction of alumina,^[106] and indirect carbothermal reduction of alumina (e.g. formation of AlCl_3 intermediate followed by Al extraction in the Alcoa process).

In this paper, a comprehensive review of various Al production methods, focusing on the indirect carbothermal reduction routes, is presented. There have been a number of major review papers on Al production routes. In 1964, Stroup^[117] provided a detailed review on the carbothermal production processes of Al. Russell^[105] provided another major review on various new technologies in 1981, including review and progress on the development of Alcoa process. This paper briefly reviews the recent development in the direct carbothermal routes followed by systematic reviews of different indirect carbothermal reduction routes. In Part 2, systematic thermodynamic analyses of selected indirect carbothermal reduction routes are presented. These include evaluation of Gibbs free energy formation and equilibrium calculations of various intermediate Al compounds and extraction of Al from these compounds.

DIRECT CARBOTHERMAL REDUCTION PROCESS

The direct carbothermal reduction of alumina to Al has potential for greater productivity, lower capital investment,

less consumption of electric power, and lower overall greenhouse gases emission, compared to the Hall–Heroult process. It is well established that direct carbothermal reduction of iron oxide, through blast furnace technology, offers far greater productivity and energy efficiency than any comparable electrolytic process. It is this desire to duplicate the merits of pyrometallurgy processing to Al that has driven interest in the carbothermal reduction of alumina. The overall reactions for carbothermal reduction of alumina can be presented as:

These two reactions are thermodynamically favoured above 2057 and 1497°C, respectively.^[117] Although these reactions look simple, in practice they are difficult to achieve with high Al yield. The reaction steps are not straight forward as intermediate and volatile subcompounds are formed during the process. During cooling down of the products, mixtures of carbide and oxycarbide can form due to reactions between the products. The chemistry and thermodynamics of the Al–C–O system have been studied extensively.^[1,2,6,11,20,28,29,44,50,53,63,68,84,86,104,116,117,127]

Recent developments in carbothermic production of Al evolved in the direction of a two-stage process. Cochran and Fitzgerald^[18] invented a stack type reactor in which Al_2O_3 and C is reacted in a high temperature upper reaction zone and produces liquid mixture of Al_2O_3 and Al_4C_3 which is then transferred to a lower reaction zone for Al extraction. Alcoa and Elkem companies thoroughly investigated carbothermic production of Al using the stack type reactor (advanced reactor process).^[3,13,31,32,36,57,58] In this process, alumina is carbothermally reduced at 2000°C in the first reaction compartment of a vessel producing liquid slag ($50\text{Al}_2\text{O}_3\text{--}50\text{Al}_4\text{C}_3$). Further reaction between alumina and Al carbide took place in the second compartment at 2200°C to produce an aluminium–carbon alloy. The reactions associated with each stage are given below

The advanced reactor process included a method for vapour recovery for recycling the Al and Al suboxide vapours generated. Fruehan et al.^[31,32] studied the mechanism and reactions of $\text{Al}_2\text{O}_{(\text{g})}$, $\text{Al}_{(\text{g})}$ with carbon source. They found that the rate of formation of Al_4C_3 from Al_2O and Al gases in CO is controlled by diffusion of the reactant gases through the Al_4C_3 product layer. In 2011, Alcoa continued the development of the carbothermal process on its own with the establishment of the Alcoa Norway Carbothermic group, in which the test reactor with auxiliary systems located at

Alcoa Lista, Southern Norway. They continue to improve the off-gas cooling system for stable operation of the reactor. White et al.^[129] reported a successful test campaigns that run for several weeks, with each tap generates several hundred kilograms of metal with total yield in tonnage scale.

Similar two-zone concept was also researched by Persson,^[98] and Dewing et al.^[23] Dmitriev and Karasev^[24] proposed an induction shaft furnace for Al_4C_3 production from alumina, where Al is then extracted by electrolysis in the lower zone of the furnace.

Other recent developments include the vacuum carbo-thermic reduction currently being developed under the ENEXAL project.^[5] This process uses an electric arc furnace with integrated shaft attachment. The electric arc furnace is the main reactor where liquid Al is produced and the shaft acts as condenser for the Al and Al_2O_3 vapours. The formation of Al rich vapour is favoured over liquid Al as the process is carried out under vacuum. The process can also be carried out at lower temperatures, e.g. 1500°C at 10 Pa pressure. Preliminary experimental study has been carried out using a solar furnace to demonstrate the process. At temperatures $1027\text{--}1727^\circ\text{C}$ and pressures 350–1200 Pa, Al (up to 19%) along with Al_4C_3 and $\text{Al}_4\text{O}_4\text{C}$ can be produced upon condensation.^[90,65] It is unclear whether yield can be improved and whether the proposed process has potential for commercialisation.

Sayad-Yaghoubi^[107] proposed a carbothermic process for the production of Al carbide by injection of carbon and Al_2O_3 into superheated Al ($>1400^\circ\text{C}$). The reaction between the injected carbon with molten Al follows

The formed Al_4C_3 attaches to Al_2O_3 and forming a mixture of $\text{Al}_4\text{C}_3\text{--Al}_2\text{O}_3$. Aluminium is extracted from the mixture in a separate zone through reaction given in Eq. 6 at $1700\text{--}2000^\circ\text{C}$. This is carried out by maintaining a sufficiently low gas pressure in the second zone, e.g. by extracting the CO gas. Sayad-Yaghoubi^[107,108,109] also proposed various type of carbonaceous materials (such as CH_4 and other hydrocarbons) and additional reactants (such Al scrap and dross) to be used in the process.

Despite the significant scientific and technological developments to date, no processes based on direct carbothermal reduction have been successfully commercialised to full plant scale. Direct carbothermal processes have to date suffered generally from problems with yield, associated with the formation of other compounds other than Al.

INDIRECT CARBOTHERMAL REDUCTION PROCESSES

Researchers and industry have also directed their attention to a multistage process, in particular indirect carbothermal reduction of alumina. This involves two or more steps where

Fig. 1 Schematic diagram showing indirect carbothermic aluminium production method from alumina

in the first step (stage 1) alumina or Al ores are converted to intermediate Al compounds. The intermediate Al compounds are then further reduced to Al metal in subsequent steps (stage 2). This is schematically shown in Fig. 1.

The following subsections review the various indirect carbothermal productions of Al, focusing on the carbochlorination, carbosulphidation and carbonitridation routes in stage 1 followed by various Al extraction techniques in stage 2.

CARBOCHLORINATION ROUTE

This route involves the formation of Al–chloride intermediate compounds from reactions of alumina (or aluminous ores) with carbon and chlorine sources. The production of volatile metal halides (including Al trichloride) from alumina has been known for many years, but most of the processes have difficulties in terms of operation and control. One of the earliest patented processes for the production of Al trichloride was from Ferguson and Cranford,^[127] where they developed a continuous process using fluidised mixture reactor. In the case of carbochlorination of alumina, the process can be represented by the following reactions

The chlorination temperature is in the range $400\text{--}1000^\circ\text{C}$ depending upon the reacting agents. There have been a number of studies on the chlorination of alumina investigating the effect of various kinetic parameters (chlorination media, partial pressure of gaseous components, particle shape and size and reactor design) on the reactions in the temperature range between 427 and 1027°C .^[9,79,80,124] Unless a high purity alumina source is used, other elements that are generally present such as iron, silicon and titanium are also chlorinated and must be separated from the Al trichloride. Yuan et al.^[139] carried out study of carbochlorination of alumina in vacuum and reported that $\text{AlCl}_{(g)}$ is formed at temperatures $1430\text{--}1580^\circ\text{C}$ at pressures $40\text{--}150$ Pa.

Grob and Richarz^[40] attempted to chlorinate alumina in kaolinitic clay in Cl_2 and CO gas mixtures. They found that the reactivity of alumina in the raw material increases when the material is first pretreated using ammonium sulphate $(\text{NH}_4)_2\text{SO}_4$ or sulphur trioxide SO_3 . At temperatures below 727°C , the chlorination rates were found to be comparable to those reported for using pure gamma alumina as starting material. However, above 727°C , SiCl_4 formed and interacted with alumina, leading to a decrease in the rate of Al chlorination.

Hauptin et al.^[46] produced Al trichloride from alumina through reaction with carbon and chlorine in alkali metal halides and alkaline earth metal halides molten salt baths (AlCl_3 – NaCl – LiCl) at temperatures 400 – 950°C . Becker and Das^[7] used a mixture of high purity activated carbon and alumina heated in bubbling chlorine at temperatures 500 – 775°C and was able to obtain 100% conversion to AlCl_3 vapour.

Toth^[123] patented a two-stage process for Al production where in stage 1, alumina is reacted with manganese chloride in the presence of carbon at temperatures 900 – 1300°C producing Al trichloride and manganese, through the reaction

Wyndham et al. (1978) and Lippman et al. (1978) (of Toth Al Corporation) used alumina based ores as the source for Al. In the case of alumina silica ores, the reaction was carried out in the presence of sulphur to improve the halogenation. Sulphur acted as a catalyst and the process could be carried out a temperature as low as 400°C through this reaction

There are other processes for Al trichloride production, including various Al extraction techniques from the chloride. Table 1 summarises selected processes and technological development associated with the chloride route (both stages 1 and 2).

EXTRACTION OF AL FROM AL TRICHLORIDE

The common routes for extracting Al from its chlorides are through disproportionation and electrolysis reactions. Other routes include distillation and direct reduction with other metals.

Disproportionation of Al Halides (Including Chlorides)

Willmore^[132] discovered that AlF_3 and several other fluorine compounds selectively distil Al at 900 – 1300°C .

Klemm and Voss^[62] indicated that this occurs because of a formation of a monovalent compound (in this case AlF) at a temperature 1200°C . This compound was then disproportionated at a lower temperature of 800°C according to the following reaction

In this process the Al condensed as a fine powder, mixed with solid AlF_3 . Therefore, further process using molten flux was necessary to separate and agglomerate the Al. It was then found that the above reaction also occurs with other Al halides. The halide formation has been the basis of Al production and refining process using various Al halides and other subcompounds. Belyayev and Firsanova^[8] conducted a survey on various Al subcompounds and concluded that subfluoride and subchloride provide the most potential for practical refining processes.

Gross^[41,42] proposed a process in which AlCl_3 vapour is passed through a bed of impure crushed Al alloy above 1000°C and Al is extracted and condensed by disproportionation at 700°C according to the reaction

The reformed AlCl_3 was not condensed and was recirculated through the reaction furnace. As only Al was condensed, further separation process from the AlCl_3 was not necessary.

In the 1960s, Alcan developed an alternative process for production of Al which involved carbothermal reduction of aluminous ores followed by monochloride purification.^[105] This work was stopped due to problems associated handling of chlorides which included stress–corrosion cracking and inefficiency in separating manganese impurities. In the 1970s, Othmer^[93,94] proposed a separation of Al from aluminous ores (bauxite, clays, feldspar) through carbochlorination (to form AlCl_3) followed by disproportionation or halogenation in a flash condenser. One of the recent works associated with carbochlorination of alumina followed by disproportionation was from Yuan et al.^[139] They carried out the carbochlorination in vacuum and observed $\text{AlCl}_{(g)}$ at temperatures 1430 – 1580°C and pressures from 40 to 150 Pa. The $\text{AlCl}_{(g)}$ was then disproportionate into Al and $\text{AlCl}_{3(g)}$ below 660°C . They were able to obtain Al metal with average purity of 95.32 wt-%.

Electrolysis of Al Trichloride

It has been claimed that Al chloride electrolysis method is attractive both from an economic and technical point of view.^[39] Ishikawa and Ichikawa^[56] argued that the potential advantages of Al chloride salt electrolysis process include:

- (i) chloride salts are much less corrosive than fluoride salts which results a longer cell life

Table 1 Summary of previous major works/patent in chloride route*

Year	Author	Reactions and parameters	Process information
2002	Tomaswick ^P (Alcoa)	AlCl ₃ molten bath with NaCl, LiCl, KCl, MgCl ₂ , CaCl ₂ , BeCl ₂ , BaCl ₂ . <i>T</i> = 300°C preferably (150–200°C) Conc. of alkali metal chloride = 10–50 mol.-%; voltage, <2.0 V; current density, >0.2 A inch ⁻²	Electrolysis of Al ₂ O ₃ in a low temperature bath containing AlCl ₃ and an alkali metal chloride. The bath is at 300°C and solid Al is produced at the cathode in the frozen layer of the alkali metal chloride (2nd stage)
2000	Sharma ^P	$\left. \begin{array}{l} \text{AlCl}_3 + 3\text{NaF} = \text{AlF}_3 + 3\text{NaCl} \\ 3\text{NaCl} = 3\text{Na} + 1.5\text{Cl}_2 \end{array} \right\} \text{AlCl}_3 = \text{Al} + 1.5\text{Cl}_2$ $\left. \begin{array}{l} \text{AlCl}_3 + 3\text{LiF} = \text{AlF}_3 + 3\text{LiCl} \\ 3\text{LiCl} = 3\text{Li} + 1.5\text{Cl}_2 \\ \text{AlF}_3 + 3\text{Li} = 3\text{LiF} + \text{Al} \end{array} \right\} \text{AlCl}_3 = \text{Al} + 1.5\text{Cl}_2$ $\left. \begin{array}{l} \text{AlCl}_3 + 3\text{KF} = \text{AlF}_3 + 3\text{KCl} \\ 3\text{KCl} = 3\text{K} + 1.5\text{Cl}_2 \\ \text{AlF}_3 + 3\text{K} = 3\text{KF} + \text{Al} \end{array} \right\} \text{AlCl}_3 = \text{Al} + 1.5\text{Cl}_2$	Electrolytic production of Al metal from Al trichloride using chloride fluoride salts bath. Al fluoride is separated from the bath and electrolytically reduced to metallic Al (2nd stage)
1990	Wilkening ^P (VAW Vereinigte Aluminium-Werke AG)	Electrolytes: Na ₃ AlF ₆ –NaCl–NaF; Li ₃ AlF ₆ –LiCl–LiF; K ₃ AlF ₆ –KCl–KF; temperature: 750°C Electrolyte melt: >50% consist of NaCl–KCl, 10–40% at least of cryolite, alkali fluorides and alkaline earth fluorides; AlCl ₃ , 3–5%. <i>T</i> = 680–850°C	Production of Al from alumina through electrolysis where the bath consists of alkali halides and/or alkali earth halides. Alumina is charged as briquette with carbon which also acts as anode. Bipolar electrodes designs are also used (2nd stage)
1986	Cohen <i>et al.</i> ^P (Pechiney)	Al ₂ O _{3(s)} + 3Cl _{2(g)} + 3C _(s) = 2AlCl _{3(g)} + 3CO _(g) <i>T</i> = 660–800°C Chlorinating gas: Cl ₂ , CCl ₄ , C ₂ Cl ₆ , phosgene Electrolysis: Conc. of AlCl ₃ in bath = 10–40 mol.-% <i>T</i> = 450–900°C	Al production method through carbochlorination of alumina, followed by electrolysis of Al trichloride in a molten salt bath containing at least one alkali/alkali earth metal halides. Flowsheet of a continuous process (1st and 2nd stages)
1986	Rao <i>et al.</i> ^P (Washington Res. Foundation)	Example for MgF ₂ catalyst: MgF _{2(s)} = MgF _{2(g)} 3Al ₂ O _{3(s)} + 2MgF _{2(g)} + 9CO _(g) + 9Cl _{2(g)} = 2MgAl ₃ F ₂ Cl _{9(g)} + 9CO _{2(g)} MgAl ₃ F ₂ Cl _{9(g)} = MgF _{2(g)} + 3AlCl _{3(g)}	The use of catalysts for carbochlorination of Al ₂ O ₃ at 750–950°C. These include: alkali fluorides, alkaline earth fluorides, alkaline earth carbonates, alkaline earth chlorides, alkaline earth bromides, alkaline earth oxides, and their mixtures (1st stage)
1981	Sinha ^P (CSIRO Australia)	Dehydration <i>T</i> = 300–400°C Chlorination <i>T</i> = 400–500°C 2AlCl ₃ ·6H ₂ O _(s) + 12CO _(g) + 12Cl _{2(g)} = 2AlCl _{3(g)} + 2CO _{2(g)} + 24HCl _(g) Gas mixture: 40–50%Cl ₂ , 30–50%CO, 5–15%CO ₂ , 5–15%H ₂	Development of a process to produce anhydrous Al chloride from Al chloride hexahydrate. The process involved dehydration and chlorination in a fluidised bed reactor (1st stage)
1981	Mueller <i>et al.</i> ^P (Swiss Al Ltd.)	Dilution agents: quartz, corundum, MgO Size: comparable to starting materials, amount 10–90 wt.-%; gas flowrates: 2–30 cm s ⁻¹ ; conversion: 58–65%	Improved carbochlorination process of aluminous ores in a fluidised bed reactor by the addition of an inert solid dilution agent to the bed (1st stage)

Table 1 Summary of previous major works/patent in chloride route* (*Continued*)

Year	Author	Reactions and parameters	Process information
1981	Loutfy <i>et al.</i> ^P (Dept of Energy of USA)	$\text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3 + 6\text{Cl}_{2(g)} + 6\text{C}_{(s)} = 2\text{AlCl}_{3(g)} + 2\text{FeCl}_{3(g)} + 6\text{CO}_{(g)}; T = 900\text{--}1200\text{ K}$ $\text{Al}_2\text{S}_{3(s)} + 2\text{FeCl}_{3(g)} = \text{Fe}_2\text{S}_{3(s)} + 2\text{AlCl}_{3(g)}; T = 800\text{ K}$ Yield: 99.8%	Production of Al trichloride from aluminous material contains iron, titanium and silicon compound reacting with carbon and a chlorine containing gas. Produced chloride gases are cooled down to 400 K or lower to condense the Al chloride and iron chloride gases then heated to 800 K and passed into intimate contact with Al sulphide to precipitate solid iron sulphide (1st stage)
1979	Ishikawa <i>et al.</i> ^P (Nippon Light Metal Co Ltd)	Electrolyte bath: $\text{CaCl}_2/\text{MgCl}_2$ (15–70 wt-%)–(15–83 wt-%)NaCl; with conc. $\text{AlCl}_3 = 2\text{--}15\text{ wt-%}$; $T = 680\text{--}780^\circ\text{C}$; current density: $0.5\text{--}2.0\text{ A cm}^{-2}$; current efficiency: 90–100%	Production of Al by electrolysis of fused Al chloride together with an alkali metal halide (2nd stage)
1978	Harvey <i>et al.</i> ^P (Westinghouse Electric Corp.)	$\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + 5\text{C} + 5\text{Cl}_2 = 2\text{AlCl}_{3(g)} + \text{SiCl}_{4(g)} + 5\text{CO}_{(g)}$ $2\text{AlCl}_{3(g)} + 3\text{Mn}_{(l)} = 3\text{MnCl}_{2(g)} + 2\text{Al}_{(l)}$ $\text{SiCl}_{4(g)} + 2\text{H}_{2(g)} = \text{Si}_{(l)} + 4\text{HCl}_{(g)}$ $\text{MnCl}_{2(g)} + \text{O}_{2(g)} = \text{Mn}_2\text{O}_{3(s)} + \text{Cl}_{2(g)}$ $\text{Si}_{(l)} + \text{Mn}_2\text{O}_{3(s)} = \text{SiO}_{2(s)} + \text{Mn}_{(l)}$ $T = 1227\text{--}1727^\circ\text{C}$	Production of Al through chlorination of chemically bonded Al_2O_3 and SiO_2 to produce AlCl_3 and SiCl_4 . AlCl_3 is then reacted with Mn to produce elemental Al and MnCl_2 . Oxidising MnCl_2 produces MnO. Reducing SiCl_4 by hydrogen to yield silicon which can be used to reduce MnO producing Mn which is recycled to the previous step to reduce AlCl_3 (1st and 2nd stage)
1978	Becker <i>et al.</i> ^P (Alcoa)	$\text{Al}_2\text{O}_{3(s)} + 3\text{Cl}_{2(g)} + 3\text{C}_{(s)} = 2\text{AlCl}_{3(g)} + 3\text{CO}_{(g)}$ Cl_2 flowrate: $0.95\text{--}3\text{ L min}^{-1}$ Chlorine to AlCl_3 : 100%; $T = 500\text{--}775^\circ\text{C}$	Production of Al chloride by using high purity activated carbon and alumina and bubbling chlorine gas. Al chloride was remove in vapour from and condensed (1st stage)
1978	Lippman <i>et al.</i> ^P (Toth Al Corp.)	$\text{Bauxite/clay}_{(s)} + \text{Cl}_{2(g)} + \text{C}_{(s)} = \text{AlCl}_{3(g)} + \text{FeCl}_{3(g)} + \text{SiCl}_{4(g)} + \text{TiCl}_{4(g)} + \text{CO}_{(g)} + \text{CO}_{2(g)}; T = 750\text{--}850^\circ\text{C}$ Vaporisation of $\text{AlCl}_3\text{--FeCl}_3$ mixture, followed by separation of AlCl_3 by distillation	Process for the production of pure Al chloride and alumina from aluminous ores through carbochlorination followed by chlorides separation and purification (1st stage)
1978	Wyndham <i>et al.</i> ^P (Toth Al Corp.)	$\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 + 7\text{C}_{(s)} + 7\text{Cl}_{2(g)} + \text{sulphur} = 2\text{AlCl}_{3(g)} + 2\text{SiCl}_{4(g)} + 7\text{CO}_{(g)}$ $T = 400\text{--}1000^\circ\text{C} (\sim 700^\circ\text{C})$	Improved halogenation of aluminous ores by sulphur treatment; allowing low temperature processing. Sulphur acts as catalyst but no detailed mechanisms were presented (1st stage)
1978	Pope ^P (Alcoa)	N/A	Development of a fluidised bed reactor for chlorination of alumina with multilayer lining (1st stage)
1977	Holliday <i>et al.</i> ^P (Comalco Ltd)	$\text{Fe}_2\text{O}_{3(s)} (\text{in bauxite}) + 3\text{SO}_{2(g)} + 7\text{CO}_{(g)} = \text{Fe}_2\text{S}_{3(s)} + \text{CO}_{2(g)}$ $\text{Fe}_2\text{S}_{3(s)} (\text{in bauxite}) + \text{Cl}_{2(g)} = \text{FeCl}_{3(g)} + \text{purified bauxite}$ $T = 430\text{--}750^\circ\text{C}$ Purified bauxite + $\text{Cl}_{2(g)} \rightarrow \text{AlCl}_{3(g)}$ (with low Fe content) $T = 650\text{--}750^\circ\text{C}$	Removal of iron from bauxite by reaction with SO_2/CO gas mixtures followed by chlorination (1st stage)
1977	Haupin <i>et al.</i> ^P (Alcoa)	$\text{Al}_2\text{O}_{3(s)} + 3\text{Cl}_{2(g)} + 3\text{C}_{(s)} = 2\text{AlCl}_{3(g)} + 3\text{CO}_{(g)}$ Molten bath: $\text{AlCl}_3\text{--NaCl--LiCl}$ Cl_2 conversion to AlCl_3 : 99%; $T = 400\text{--}950^\circ\text{C}$	Production of Al chloride by reaction of Al oxide, carbon and chlorine in an alkali metal halides and alkaline earth metal halides molten salt bath. Al chloride was separated by vaporisation (1st stage)

Table 1 Summary of previous major works/patent in chloride route* (*Continued*)

Year	Author	Reactions and parameters	Process information
1975	Terry <i>et al.</i> ^p (Toth Al Corp.)	$3\text{Mn}_{(s)} + 2\text{AlCl}_{3(g,l)} = 3\text{MnCl}_{2(s,\text{soln})} + 2\text{Al}_{(s)}$ Pressure range: 15–450 psi; temperature: 180–600°C; time: ~2h; AlCl_3 flowrate: 0.75–3.20 g h ⁻¹	A method of producing Al wherein Al chloride in liquid phase reacted with manganese in solid phase. The manganese reduces Al chloride and forms essentially elemental Al and manganese chloride (2nd stage)
1975	Dell <i>et al.</i> ^p (Alcoa)	$\text{AlCl}_{3(l)} = \text{Al}_{(l)} + 1.5\text{Cl}_{2(g)}$ Electrolyte: 50–75%NaCl and 25–50%LiCl ₂ ; Conc. AlCl_3 : 1.5–10 wt-%; $T = 660\text{--}730^\circ\text{C}$	Design and development of electrolytic cell with intermediate bipolar electrodes. This allows the flow of bath melt and settling of Al metal. Anode–cathode distance/spacing of less than 3/4 inch (2nd stage)
1975	Othmer ^p	$3\text{AlCl}_{(g)} = 2\text{Al}_{(l)} + \text{AlCl}_{3(g)}$ $2\text{AlCl}_{3(g)} + 6\text{S}_{(l)} = 2\text{Al}_{(l)} + 3\text{S}_2\text{Cl}_{2(g)}$ $T = 600\text{--}1000^\circ\text{C}$ Other reactions above 1500°C: $\text{Al}_2\text{O}_{3(s)} + \text{S}_2\text{Cl}_{2(g)} + 3\text{C}_{(s)} = 2\text{AlCl}_{(g)} + 2\text{S}_{(l)} + 3\text{CO}_{(g)}$ $2\text{Al}_2\text{O}_{3(s)} + 2\text{S}_2\text{Cl}_{2(g)} + \text{O}_{2(s)} = 4\text{AlCl}_{(g)} + 4\text{SO}_{2(g)}$	Extraction of Al from Al trihalide by halogenation and/or disproportionation in a flash condenser (2nd stage)
1974	Othmer ^p	$\text{Cl}_{2(g)} + \text{Al}_2\text{O}_{3(s)} + 3\text{C}_{(s)} = 2\text{AlCl}_{(g)} + 3\text{CO}_{(g)}$ $\text{SiCl}_{4(g)} + 2\text{Al}_2\text{O}_{3(s)} + 4\text{C}_{(s)} = 4\text{AlCl}_{(g)} + 4\text{CO}_{(g)} + \text{SiO}_{2(s)}$ $\text{AlCl}_{3(g)} + \text{Al}_2\text{O}_{3(s)} + 3\text{C}_{(s)} = 3\text{AlCl}_{(g)} + 3\text{CO}_{(g)}$ $T = 1000\text{--}1200^\circ\text{C}$ Removal of Fe impurities: $2\text{AlCl}_{2(g)} + \text{Fe}_2\text{O}_{3(s)} = 2\text{FeCl}_{3(g)} + \text{Al}_2\text{O}_{3(s)}$ Disproportionation $T = 700^\circ\text{C}$ $3\text{AlCl}_{(g)} = 2\text{Al}_{(l)} + \text{AlCl}_{3(g)}$	Separation of Al from aluminous ores (bauxites, clays, feldspar, etc) through the formation of volatile tri-halide, followed by disproportionation of tri-halide to metallic Al. (1st and 2nd stages)
1973	Russell <i>et al.</i> ^p (Alcoa)	$\text{AlCl}_{3(l)} = \text{Al}_{(l)} + 1.5\text{Cl}_{2(g)}$; $T = 660\text{--}730^\circ\text{C}$ Electrolyte: NaCl–LiCl ₂ (50:50, w/w) Cone. AlCl_3 in bath: 1–15 wt-%; oxide impurities: <0–25 wt-% ACD: 1 in; current density: 10 A; voltage: <5 V; current efficiency: 80%	Production of Al by continuous electrolysis of Al trichloride. Increase of current efficiency of the process (avoiding the formation of sludge) using proposed operating conditions (2nd stage)
1971	Toth ^p (Applied Al Research Corp.)	$\text{Al}_2\text{O}_{3(s)} + 3\text{MnCl}_{2(l)} + 3\text{C}_{(s)} = 3\text{Mn}_{(l)} + 2\text{AlCl}_{3(g)} + 3\text{CO}_{(g)}$ $3\text{Mn}_{(l)} + 2\text{AlCl}_{3(g)} = 2\text{Al}_{(l)} + 3\text{MnCl}_{2(l)}$ $T = 900\text{--}1300^\circ\text{C}$	Production of Al by a two-steps process comprising the reaction of alumina with manganese chloride in the presence of carbon to form Al trichloride and manganese and the subsequent reaction of Al trichloride with manganese at a temperature sufficient to reduce Al trichloride to Al (1st and 2nd stages)
1948	Ferguson <i>et al.</i> ^p (Standard Oil Development Co)	$\text{Al}_2\text{O}_{3(s)} + 3\text{C}_{(s)} + 3\text{Cl}_{2(g)} = 2\text{AlCl}_{3(g)} + 3\text{CO}_{(g)}$ $T = 649\text{--}816^\circ\text{C}$	Production of Al chloride and Al bromides. Development of a continuous process using a ‘fluidised mixture’ type reactor (1st stage)
1939	Willmore ^p (Alcoa)	$3\text{AlF}_{(l)} = 2\text{Al}_{(s)} + \text{AlF}_{3(s)}$ $T = 900\text{--}1000^\circ\text{C}$	Disproportionation of Al halides, including Al chlorides (2nd stage)

- (ii) the electrolysis process requires a closed system which limit the emission of gasses
- (iii) chloride salts have higher conductivities compared to the fluoride salts resulting lower energy consumption, higher power and current efficiencies
- (iv) the electrolysis process has a very broad operational range of Al concentration which results in no 'anode effect'
- (v) it is possible to design an electrolytic process cell with bipolar electrodes which results in a much more compact cell with increased production potential per unit volume

In the 1970s, Alcoa developed alternative processes to produce Al which focused in three major directions:

- (i) direct carbothermal reduction of alumina
- (ii) indirect carbothermal reduction of aluminous ores that involved carbochlorination, monochloride purification
- (iii) electrolysis of Al chloride^[105]

The general schematic of the process routes is shown in Fig. 2.

Russell et al.^[106] from Alcoa developed an Al chloride electrolysis process using NaCl–LiCl (50:50, w/w) electrolyte at temperatures 660–730°C. They suggested operation with 1–15 wt-% concentration of AlCl₃ in the bath. The anode–cathode distance in the process was suggested to be ~25 mm. They were able to improve the current efficiency (up to 80%) and avoid the formation of sludge from the impurities using these proposed operating conditions. Dell et al.^[21] improved the process by developing a new design with bipolar electrodes. This allowed the process to operate with a lower anode–cathode distance (<19 mm). Alcoa developed the Al trichloride electrolysis route in the 1970s to a commercial level but halted the operations in the 1980s, because of difficulties associated with production and handling of pure Al trichloride.^[121]

Ishikawa and Ichikawa^[56] from Nippon Light Metal electrolysed AlCl₃ in a molten AlCl₃–LiCl–NaCl salt bath

at 700°C. Additions of LiCl, CaCl₂ or MgCl₂ salts to the bath improved the electrical conductivity and the current efficiency. They were able to obtain 90–100% current efficiency. Cohen et al.^[19] from Pechiney proposed a continuous process through carbochlorination of alumina to form AlCl₃ followed by electrolysis in AlCl₃–alkali/alkali–earth metal halides electrolyte. One of the recent works on the electrolysis of AlCl₃ was from Sharma^[112] where Al is produced through electrolysis in a chloride–fluoride salt bath at 750°C. The electrolytes used include Na₃AlF₆–NaCl–NaF, Li₃AlF₆–LiCl–LiF and K₃AlF₆–KCl–KF.

Wilkening^[131] produced Al through electrolysis where the bath consists of alkali halides and/or alkali earth halides. A mixture of Al oxide and carbon was used as a feed material. Different arrangements of the electrolytic cell were also proposed in the work. Tomaswick^[122] from Alcoa electrolysed Al₂O₃ directly in a bath containing AlCl₃ and an alkali metal chloride (NaCl, LiCl, KCl, MgCl₂, CaCl₂, BeCl₂, BaCl₂). The process was carried at 300°C and Al was extracted as a solid metal at the cathode in a frozen layer of the alkali metal chloride.

Other Al Extraction Methods from Al Trichloride

There are other methods used to extract Al from AlCl₃. One example is through direct reduction using another metal (e.g. manganese). Toth^[123] patented a two-stage process where in stage 1, alumina is reacted with manganese chloride in the presence of carbon producing Al trichloride and manganese, as given in reaction in Eq. 10. The Al was extracted by reacting AlCl₃ with manganese in stage 2 at a temperature sufficient to reduce AlCl₃ to Al, according to the following reaction

The flowsheet of the process is shown in Fig. 3. Terry et al.^[120] modified the process and carried out the reaction at lower temperatures (180–600°C) and higher pressures (0.1–3.04 MPa)

Fig. 2 Schematic diagram showing process routes considered by Alcoa^[105]

Fig. 3 Flowsheet of Toth process^[123]

using solid manganese to form solid Al directly according to the reaction

CARBOSULPHIDATION ROUTE

Another alternative Al production method that has received a less attention is through the formation of Al sulphides (Al_2S_3 and AlS) as intermediate compounds. One of the first patented processes on the carbothermic production of Al_2S_3 was by Haglund.^[43] Haglund produced a mixture of Al_2O_3 and Al_2S_3 from the reaction between Al_2O_3 containing ores, carbon as reduction agent, and sulphur sources in the form of FeS and ZnS. FeS was added in the form of a lump (mixed with uncalcined bauxite) where it was sink through the formed slag into the liquid iron alloy underlying the slag. Al sulphide was formed as part of the reaction products, while Al was contained in the iron alloy.

Weiss^[128] proposed a method for producing Al from a mixture of aluminous ores and Al_2S_3 reacted with carbon at temperatures above 1000°C at pressures below atmospheric pressure. The reaction resulted in vapours of Al subsulphide (such as Al_2S) which upon cooling disproportionated into Al sulphide (Al_2S_3) and Al precipitate. The reactions are given below

Weiss proposed the process to be carried out at $1000\text{--}1200^\circ\text{C}$ at pressure below 5 mmHg. The process could be carried out at higher pressures if the temperature of the process is increased, e.g. at a temperature above 2000°C , the process can be carried out at atmospheric pressure.

Loutfy et al.^[77] studied the thermodynamics of the carbosulphidation of alumina and patented an Al production process in 1981.^[76] Aluminous ores were reacted with carbon and sulphur containing gas at temperatures

$1027\text{--}1227^\circ\text{C}$ to obtain molten Al sulphide (Al_2S_3) and CO gas according to the following reaction

The Al_2S_3 was further heated at temperatures $1327\text{--}1627^\circ\text{C}$ to produce Al monosulphide (AlS) and sulphur. Then AlS was cooled to a temperature $927\text{--}1097^\circ\text{C}$ where it disproportionated to molten Al sulphide (Al_2S_3) and Al metal following the reactions

The $\text{Al}_2\text{S}_{3(l)}$ produced from the reaction in Eq. 20 was then electrolysed to extract the Al. The flowsheet of the process is shown in Fig. 4.

Fig. 4 Flowsheet of aluminium production through carbosulphidation followed by combination of disproportionation and electrolysis proposed by Loutfy et al.^[76]

Sportel and Verstraten^[115] (of Corus Al GmbH) produced Al_2S_3 from $\gamma\text{-Al}_2\text{O}_3$ using CS_2 gas at 850°C according to the following reactions

The carbon disulphide is produced by reacting methane with sulphur gas through the following reactions

The process is preferably performed at temperatures of $750\text{--}1100^\circ\text{C}$ and pressures of $5 \times 10^5\text{--}35 \times 10^5$ Pa.

Typically temperature of 850°C and pressure of 30×10^5 Pa are applied if solid Al_2S_3 is required.^[115] This temperature was proposed to avoid transformation of $\gamma\text{-Al}_2\text{O}_3$ to $\alpha\text{-Al}_2\text{O}_3$. It was shown that the reaction rate between $\gamma\text{-Al}_2\text{O}_3$ and $\text{CS}_{2(g)}$ is higher compared to that of reaction between $\alpha\text{-Al}_2\text{O}_3$ and $\text{CS}_{2(g)}$. It was proposed that the resulting Al_2S_3 is to be electrolysed to extract the aluminium. This route (carbosulphidation followed by electrolysis) is the basis of the Corus – Compact Aluminium Production Process (CAPP). The proposed flowsheet for this process is shown in Fig. 5.

Xiao et al.^[137] studied the kinetics of the sulphidation of alumina with CS_2 gas at ambient pressure. They suggested that the optimum temperature of 850°C for sulphidation of $\gamma\text{-Al}_2\text{O}_3$. In the experimental conditions studied, they reported that the particle size of $\gamma\text{-Al}_2\text{O}_3$ has no effect on the reaction rate. A maximum conversion ratio of $\sim 40\%$ after 5 h reaction at the conditions studied was reported.

Li et al.^[71,72] investigated the possibility of direct formation of Al monosulphide (AIS) by reacting alumina–carbon mixture with FeS according to the following reaction

They suggested the above reaction can be carried out at temperatures as low as $407\text{--}597^\circ\text{C}$ at pressure range of $15\text{--}300$ Pa.

Previous major works on the production of Al from alumina (or aluminous ores) through carbosulphidation reactions followed by various Al extraction process (stages 1 and 2) are summarised in Table 2.

EXTRACTION OF AL FROM AL SULPHIDES

The literature review on the production of Al through carbosulphidation route revealed that the methods proposed to extract Al from its sulphides are disproportionation and electrolysis.

Disproportionation of Al Subsulphides

The basis of Al extraction by disproportionation is through dissociation of Al subsulphides to Al sulphide (Al_3S_2) and Al upon cooling (e.g. at temperature below the disproportionation temperature of associated subsulphides). Weiss^[128] suggested the disproportionation of $\text{Al}_2\text{S}_{(g)}$ subsulphide as per reaction given in Eq. 17 at pressure 5 mmHg and temperature of 1200°C . Loutfy et al.^[77] proposed the extraction of liquid Al through disproportionation of $\text{AlS}_{(l)}$ subsulphide at temperatures between 927 and 1097°C following reaction in Eq. 20. Loutfy et al.^[77] did not provide information on the pressure for the process. Thermodynamic analysis carried out by Dewan et al.^[22] showed that the reaction in Eq. 20 does not occur at ambient pressure. Although mentioned in a number of patents,^[77,128] there is a limited published work on the details of thermodynamics and kinetics of the disproportionation reactions of Al subsulphides. Further studies on the thermodynamics and kinetics of Al subsulphide disproportionation are needed for optimisation of the process.

Fig. 5 Flowsheet of compact aluminium production process (CAPP)^[115]

Table 2 Summary of previous major works/patents in sulphide route*

Year	Author	Reactions and process parameters	Process details
2007	Xiao <i>et al.</i>	$\text{Al}_2\text{S}_3 = 2\text{Al} + 1.5\text{S}_{2(\text{g})}$ Electrolytes: MgCl_2 – NaCl – KCl Temperature: 700°C Yield: 42%, current efficiency: 62% Energy required: 13.4 kWh kg^{-1}	The electrochemical behaviour of Al_2S_3 in molten salt on a laboratory scale. Temperature and cryolite addition have a positive effect on the current density (2nd stage)
2006	van der Plas <i>et al.</i> ^p (Corus Aluminium)	Temp: 800 – 900°C Pressure: $\geq 3 \times 10^5 \text{ Pa}$ Salt mixture: KCl – NaCl – $10 \text{ wt-\%}$ cryolite Sulphidation gas: mainly CS_2	Continuous production of Al from alumina including a first step of converting alumina into Al sulphide (Al_2S_3) and a second step of separation of Al from Al sulphide in a separating reactor. In the first step, alumina is dissolved in a molten salt. Sulfur containing gas is fed through the melt. It is proposed that Al extraction is carried through electrolysis in multipole cell (1st and 2nd stages)
2004	Xiao <i>et al.</i>	$\text{CH}_4(\text{g}) + 2\text{S}_2(\text{g}) = \text{CS}_2(\text{g}) + 2\text{H}_2\text{S}(\text{g})$ $\text{Al}_2\text{O}_3(\gamma) + 3\text{CS}_2(\text{g}) = \text{Al}_2\text{S}_3 + 3\text{CO}(\text{g}) + 1.5\text{S}_2(\text{g})$ $\text{Al}_2\text{S}_3 = 2\text{Al} + 1.5\text{S}_2(\text{g})$ Sulphidation $T = 850^\circ\text{C}$; yield: 40%	Investigation of sulphidation kinetics of Al_2O_3 with CS_2 gas. The alumina with a higher specific surface area results in a higher sulphidation ratio. The particle size of γ - Al_2O_3 has no effect on the reaction ratio (1st and 2nd stages)
2004	Van Der Plas ^p (Corus Technology BV)	Cathode: $\text{Al}^{3+} + 3\text{e}^- = \text{Al}$ Anode: $2\text{S}_{2-} = \text{S}_{2(\text{g})} + 4\text{e}^-$ Overall: $\text{Al}_2\text{S}_3 = 2\text{Al} + 1.5\text{S}_{2(\text{g})}$ Electrolytes: MgCl_2 – NaCl – KCl $T = 700$ – 800°C ; current efficiency: 80%	Production of Al by electrolysis of Al_2S_3 in multipolar cell, using a molten chloride salt bath. The sulphur gas was collected and recycled to produce CS_2 which was used in the sulphidation step. MgCl_2 is added to the bath to increase solubility of Al_2O_3 . Cryolite may also be added (2nd stage)
2003	Sportel <i>et al.</i> ^p (Corus Aluminium)	$3\text{H}_2\text{S} + 1.5\text{O}_2 = 3\text{S} + 3\text{H}_2\text{O}$ $\text{CH}_4 + 2\text{S}_2 = \text{CS}_2 + 2\text{H}_2\text{S}$ ($T = 550$ – 650°C) $2\text{Al}_2\text{O}_3 + 6\text{CS}_2 = 2\text{Al}_2\text{S}_3 + 6\text{CO} + 3\text{S}_2$ $\text{Al}_2\text{O}_3 + 3\text{CS}_2 = \text{Al}_2\text{S}_3 + 3\text{COS}$ $T = 750$ – 1000°C ; $P = 1 \times 10^5$ – $40 \times 10^5 \text{ Pa}$	Production of primary Al from alumina comprising the step of converting alumina into Al sulphide (Al_2S_3) and subsequently Al is separated from Al sulphide. γ -alumina is preferred for the reaction due to better kinetics. Three reactors were proposed: for manufacturing CS_2 , for manufacturing Al_2S_3 from Al_2O_3 and CS_2 and electrolysis cell for Al extraction (1st stage)
1984	Minh <i>et al.</i> ^p (Dept of Energy of USA)	$\text{MgCl}_{2(\text{soln})} + \text{Al}_2\text{S}_{3(\text{s})} = 2\text{AlSCl}_{(\text{soln})} + \text{MgS}(\text{s})$ Temperature: 700 – 800°C ; voltage: < 2 – 3 V Conc. Al_2S_3 in bath 2–10 mol.-% Electrolytes: (20–70 mol.-%) MgCl_2 – NaCl – KCl MgCl_2 – NaCl – KCl –(1–10 mol.-%) AlCl_3 Current efficiency: 75–85%	Production of Al through electrolysis of Al_2S_3 utilising an electrolytic bath containing alkali metal chloride and/or alkaline earth metal chloride to provide improved operating characteristics of the process (2nd stage)
1981	Loutfy <i>et al.</i> ^p (Dept of Energy of USA)	$\text{Al}_2\text{O}_3 + 3\text{C} + 3\text{S} = \text{Al}_2\text{S}_3 + 3\text{CO}$; $T = 1027$ – 1227°C $\text{Al}_2\text{S}_3 = 2\text{AlS} + \text{S}$; $T = 1327$ – 1627°C $3\text{AlS} = \text{Al}_2\text{S}_3 + \text{Al}$; $T = 927$ – 1097°C	Al ore is reacted with carbon and sulphur containing gas at elevated temperatures forming molten Al sulphide which is decomposed to Al subsulphide (AlS). Then Al monosulphide is cooled to below its disproportionation temperature to produce Al metal. Blended aluminous ores and coke were used (1st and 2nd stages) Note: current thermodynamic analyses indicate that the proposed reactions of the 2nd stage of the process do not occur at the conditions specified

Table 2 Summary of previous major works/patents in sulphide route* (Continued)

Year	Author	Reactions and process parameters	Process details
1958	Weiss ^p (Vereinigte Aluminium-Werke AG)	$2\text{Al}_2\text{O}_{3(s)} + \text{Al}_2\text{S}_3(s) + 6\text{C}_{(s)} = 3\text{Al}_2\text{S}_{(g)}$ $+ 3\text{CO}_{(g)}$ $3\text{Al}_2\text{S}_{(g)} = \text{Al}_2\text{S}_{3(g)} + 4\text{Al}_{(s)}$ $T = 1000\text{--}1200^\circ\text{C}$ at $P < 5$ mmHg $T > 2000^\circ\text{C}$ at $P = 0.1$ MPa	Production of Al from aluminous ores by reactions of a mixture of aluminous ores, Al_2S_3 and carbon. The reaction produce vapours of Al subsulphide which upon cooling produce Al sulphide and Al precipitate (1st and 2nd stages)
1931	Haglund ^p	N/A	Production of mixture of Al_2O_3 and Al_2S_3 by reaction between Al_2O_3 containing materials, reduction agents (carbon) and sulphur sources (FeS, ZnS) (1st stage)

*Prefers to patent; 1st stage refers to production of intermediate Al sulphides; 2nd stage refers to extraction of Al from the sulphides.

Electrolysis of Al Sulphide

The extraction of Al metal by electrolysis of Al sulphide in molten salts is attractive from the viewpoint of energy utilisation. By improving the cell design and electrolyte composition, the theoretical energy consumption can be reduced to 8.41 kWh kg^{-1} Al which is considerably lower than the value of 14 kWh kg^{-1} Al in the current Hall–Heroult process.^[136] Al sulphide ($\text{Al}_2\text{S}_{3(s)}$) has a lower theoretical decomposition potential, compared to $\text{Al}_2\text{O}_{3(s)}$ and $\text{AlCl}_{3(l)}$ (Minh *et al.* 1982), and can be electrolytically decomposed in a molten cryolite at $727\text{--}927^\circ\text{C}$ ^[76] to produce molten Al and sulphur gas that can be recycled for CS_2 production.

The early works on the electrolysis of Al_2S_3 in a mixture of cryolite with NaCl were from German and Russian scientists (in 1930s and early 1940s). In these studies, a maximum current efficiency of 55% was reported.^[60,61,103] The overall reaction for electrolysis of Al_2S_3 in molten electrolyte follows

In the early 1980s, Minh *et al.*^[81,82] electrolysed Al_2S_3 to extract Al in an electrolytic bath containing alkali metal chloride and alkaline earth metal chlorides ($\text{MgCl}_2\text{--NaCl--KCl}$ and $\text{MgCl}_2\text{--NaCl--KCl--AlCl}_3$). They carried out the process at 750°C and found out that the limiting current density for the process was at the graphite anode. Within the current density range investigated ($0.2\text{--}1.2 \text{ A cm}^{-2}$), current efficiencies of 75–85% were claimed. Minh *et al.*^[83] further patented the work in 1984. In this work, it was suggested that the process be carried out at $700\text{--}800^\circ\text{C}$, with MgCl_2 concentrations of 20–70 mol.-% with a balance of NaCl, KCl and AlCl_3 . The solubility of the Al_2S_3 is $\sim 3 \text{ wt.-%}$ at 750°C , but could be enhanced by the presence of MgCl_2 and AlCl_3 according to the following reactions

In the 2000s, Corus developed a process for Al extraction through electrolysis of Al_2S_3 , as part of development of the CAPP process. Lans^[69,135] electrolysed Al_2S_3 and obtained Al melt and sulphur gases at the anode according to reaction given in Eq. 26. A molten electrolyte of $\text{MgCl}_2\text{--NaCl--KCl}$ (50:30:20, mol/mol/mol) was used and cryolite ($\sim 10 \text{ wt.-%}$) was added to enhance the solubility of Al_2S_3 and increase the activities of Al and S in the melt. This resulted in an increase in the current density up to three times. This work was the basis of the Corus patent.^[125] Further studies were carried out by^[136] to investigate in detail the mechanism of the process. It was concluded that the electrolytic process was governed by its ohmic drop. The production of sulphur bubbles at the anode was suggested to significantly affect the ohmic drop. Addition of cryolite changed the characteristic of the sulphur bubbles layer thus decreasing the ohmic drop. Increased Al_2S_3 solubility due to the cryolite addition resulted in a higher limiting current density. It was reported that a current efficiency of 62% can be achieved.

In 2006, Corus^[126] developed a continuous production process of Al from alumina. In the first stage, alumina was dissolved in a molten salt and a sulphur containing gas (in particular CS_2) was fed through the melt; this resulted in a partial conversion of alumina to Al sulphide. Al was then separated from Al sulphide in a multipole electrolysis cell. The process was carried out at temperatures $800\text{--}900^\circ\text{C}$, at pressures above $3 \times 10^5 \text{ Pa}$ in a $\text{KCl--}10 \text{ wt.-%NaCl}$ cryolite mixture.

CARBONITRIDATION ROUTE

Selvaduray and Sheet^[110] and Haussonne^[47] provided a review on various methods for the synthesis of Al nitride. In general the methods can be classified into: carbonitridation reactions, direct nitridation, floating nitridation, chemical vapour deposition, vapour phase reactions and reactions utilising organometallic precursors.^[110] Only the carbonitridation route will be described in this paper, as it is the route most relevant to industrial scale production of metal.

Carbonitridation of alumina and aluminous ores is a well known process. It follows an overall reaction of

Rather than for Al production, the original aim of the process was to produce Al nitride or to purify alumina from its ores. In the later case, for example in the Serpek^[111] process, a mixture of bauxite and coke is heated in an electric furnace in the presence of nitrogen to produce Al nitride. Al nitride can then be hydrolysed through reaction with water to form pure alumina and ammonia. The reaction can be carried out even at ambient temperature^[48,71,72] but at slow reaction rates.^[34]

Considerable disagreement exists in the literatures concerning the detailed reaction steps for nitride formation. Hirai et al.^[49] synthesised $\text{AlN}_{(s)}$ from $\text{Al}_2\text{O}_{3(s)}$ and graphite at temperatures between 1500 and 1700°C. They observed a small quantity of Al oxynitride (AlON), when alumina graphite mixture is heated at 1700°C. Their results indicated that the reaction rate is not affected by the grain size of graphite, pellet diameter and flow rate of N_2 ; and they suggested that the diffusion of the reactant gas through the $\text{AlN}_{(s)}$ layer (formed around $\text{Al}_2\text{O}_{3(s)}$) is the rate determining step. Lefort and Billy^[70] argued that the rate determining step suggested by Hirai *et al.* is unlikely as the apparent activation energy ($\sim 530 \text{ kJ mol}^{-1}$) is beyond what would be expected from a limiting gaseous diffusion. They suggested that the rate limiting process is the combustion of carbon and suggested the following reaction steps

The dissociation of alumina was suggested to be controlled by the very low partial pressure of oxygen in contact with carbon, and followed by fast nitridation of the Al vapour formed. Lefort and Billy^[70] recommended temperatures 1550–1600°C for the process. Chen and Lin,^[14] studied a carbonitridation of alumina at temperatures 1375–1552°C and developed a kinetic model for the process. A mixed mechanism was proposed comprising reaction between $\text{Al}_2\text{O}_{3(s)}$ and $\text{C}_{(s)}$ to form $\text{Al}_2\text{O}_{(g)}$ and $\text{CO}_{(g)}$, followed by surface reaction between $\text{Al}_2\text{O}_{(g)}$ and $\text{N}_{2(g)}$ to form $\text{AlN}_{(s)}$.^[14,15] They suggested that the formation of $\text{Al}_2\text{O}_{(g)}$ is the rate limiting step according to

Al monocyanoide, $\text{AlCN}_{(s)}$, can also form as described by Perieres and Bollack^[97] according to

A preferred temperature of 1700°C was recommended for nitride preparation as the formation of $\text{AlCN}_{(g)}$ increases above 1700°C, which explains the apparent decrease in nitride formation and the presence of Al carbide in the condensates.^[97] Al monocyanoide vapour can react with Al vapour forming solid encrustations of carbide and nitride.

Ide et al.^[55] produced $\text{AlN}_{(s)}$ through carbonitridation of alumina at temperatures 1350–1450°C using $\text{CaF}_{2(s)}$ as catalyst. They reported that nitridation rate tended to increase with decreasing particle size of alumina and was affected by the history of the alumina used in the reaction. They observed the formation of intermediate compounds $\text{CaO} \cdot 6\text{Al}_2\text{O}_3$ (CA_6) and $\text{CaO} \cdot 2\text{Al}_2\text{O}_3$ (CA_2) and suggested that the process proceeded through the nitridation of the intermediate compounds from liquid phase system CaF_2 – CA_6 – CA_2 . Molisani and Yoshimura^[85] investigated the effect of various additives (0.5–3 wt-% CaF_2 , Y_2O_3 , Li_2CO_3 and SrCO_3) on the carbonitridation of alumina at 1300–1400°C. The addition of these additives (and their mixture combinations) was reported to reduce the synthesis temperature by a maximum of 200°C. They attributed this to the formation of aluminate phases that easy to vapourise at lower temperatures.

Bartnitskaya et al.^[6] studied the carbonitridation reaction at temperatures 1800–1900°C in a static condition (closed system) under nitrogen atmosphere of 0.2–0.3 MPa. They obtained isometric AlN particles of 2–6 μm as opposed to fibrous type particles usually obtained in reaction carried out in a stream of nitrogen gas. They suggested that in the case of reaction at a high nitrogen pressure, alumina dissociation is suppressed which excludes the possibility of reaction in the gas phase, hence the formation of isometric particles. Chowdhury et al.^[16] synthesised nanosize $\text{AlN}_{(s)}$ by nitridation of C– Al_2O_3 composite particles at 1500–1600°C in an over pressure (0.4 MPa) flowing nitrogen gas. A mixture of fibrous and spherical particles was obtained.

Joo and Jung^[59] investigated the effect of CO content in the N_2 –CO gas mixture for carbonitridation reaction from 1000 to 1600°C. They used Al hydroxosuccinate as precursor for the reaction. The carbonitridation reaction was found to be retarded with increasing content of CO in the mixed gas. They observed conversion sequence from ρ - Al_2O_3 to γ - Al_2O_3 to $\text{AlN}_{(s)}$ (or to δ - Al_2O_3) depending on the CO content in the gas mixture. Qin et al.^[95] prepared C– Al_2O_3 composite particles from $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, $\text{CO}(\text{NH}_2)_2$ and $\text{C}_6\text{H}_{12}\text{O}_6 \cdot \text{H}_2\text{O}$ and carried out the nitridation at 1000–1600°C in a flowing nitrogen gas. They reported a conversion to γ - Al_2O_3 followed by direct conversion to $\text{AlN}_{(s)}$ upon nitridation. Complete conversion was observed at 1400°C.

Galvez et al.^[34] produced $\text{AlN}_{(s)}$ using concentrated thermal radiation through reduction of Al_2O_3 using activated C (and CH_4) in flowing nitrogen. The radiative fluxes used

were equivalent to solar concentration exceeding 4500 kW m⁻² and the reaction was carried out at 1827–2027°C. In the case of carbothermal–nitridation reaction (reaction given in Eq. 28), the experimental data were fitted into a solid–solid reactions model with an apparent activation energy of 360 kJ mol⁻¹. In the case of reduction using CH₄ (methanothermal reduction), the overall reaction follows

In this case, a low conversion (~10%) was observed. It was suggested that the diffusion is hindered by a carbon layer produced from the decomposition of CH₄. The kinetics, however, may be enhanced by doping the alumina with metallic particles (such as Ni and Fe). Best results were obtained when Ni is used, where it acts as nucleation site for carbon filament growth.

Galvez et al.^[33] also investigated the carbothermal reduction of alumina in nitrogen atmosphere at temperatures between 1500 and 1700°C. The kinetics were described as solid–solid reactions and fitted to Jander and Ginstling–Brounshtein models with activation energies of 815 and 757 kJ mol⁻¹ respectively. They also evaluated various types of carbon sources and reported that the reaction rates vary for different carbons (listed in decreasing order of reaction rates: petcoke, activated carbon, wood charcoal and carbon black).^[35]

Baik et al.^[4] and Kuang et al.^[66] produced Al nitride through carbonitridation using sucrose precursors. Zhang and Gao^[140] produced nanocrystalline Al nitride from δ -Al₂O₃ nanoparticles in flowing ammonia. They reported that the nanocrystalline δ -Al₂O₃ was converted into AlN_(s) completely at temperatures 1350–1400°C within 5 h in a single step synthesis process. Xi et al.^[134] synthesised AlN_(s) by carbothermal reduction using a mechanically activated Al₂O₃. They showed that carbonitridation can be carried out at temperature as low as 1100°C and completed thoroughly at 1250°C when milled Al₂O₃ (for 20 h) was used.

There are two primary methods to prepare AlN powders at an industrial scale:^[110] direct nitridation of Al with N₂ (2Al + N₂ = 2AlN), and carbothermal reduction of Al₂O₃ with carbon black (or other carbonaceous sources) in the presence of N_{2(g)} at 1500–2000°C (reaction in Eq. 29). The former is beyond the scope of this paper. In terms of technological developments, a number of Al nitride production processes by carbonitridation in nitrogen or mixed gas atmosphere have been patented. A summary of these studies is presented in Table 3.

One of the first patents in the carbonitridation of alumina is from Shold in 1918 where he carried out the reaction at 1800–2000°C. In the 1960s, Pechiney^[17,97] (Paris *et al.*, 1986) patented various carbonitridation processes. Perieres and Bollack^[97] produced AlN powder to 99% by roasting the produced AlN_(s) from carbonitridation reaction in an oxygen free atmosphere at 700–800°C

to burn off the excess carbon. Clair^[17] developed a vertical shaft counter current reactor for continuous production of Al nitride, while Paris and Perieres (1986) used a mixed environment of nitrogen and hydrocarbon gas for carbonitridation of alumina at 1200–1700°C. The hydrocarbon gas was cracked to elemental carbon in a highly reactive state in uniform distribution throughout the Al oxide particle.

Kuramoto et al. (1986) produced AlN powder from alumina and carbon by firing the mixture at 1400–1700°C in nitrogen (or ammonia) atmosphere followed by heating at 600–900°C to improve the purity to 94%. Bolt^[10] patented a method to produce Al nitride films (and fibres) using precursors containing alumina and carbon.

In the 1990s, a number of AlN_(s) production processes were patented by various companies. Nakano et al.^[91] patented a process using very fine source materials (<5 μm). Dunn et al.^[26] increased the purity of AlN_(s) produced by carbonitridation by applying mechanical agitation. Most of the impurities remain in the outer zone of the pellet and a significant amount of the surface portion is removed to improve the purity of the final Al nitride product. Dorn *et al.* (1996) produced AlN_(s) through calcinations of Al hydroxide–carbon mixtures at temperatures from 400 to 1000°C followed by nitridation from 1400 to 1700°C. Ravenel et al.^[101,102] patented a process for continuous production of Al nitride from 1350 to 2000°C using a moving bed reactor. Kotaka et al.^[64] patented a process to produce AlN_(s) from γ -Al₂O₃ using mixtures of ammonia and hydrocarbons from 1200 to 1700°C and claimed to obtain purity of 99%.

EXTRACTION OF AL FROM AL NITRIDE

One of the ways to extract aluminum from aluminum nitride is through thermal dissociation. The thermal dissociation of Al nitride occurs at a temperature above 2400°C at 0.1 MPa according to reaction

The temperature of the dissociation can be reduced by operating the process at lower pressures or in a vacuum condition. Thermodynamic calculations^[22] showed that the dissociation temperature can be reduced to ~1700°C if the pressure is reduced to 0.1 kPa.

The theoretical decomposition voltage of Al nitride to Al and nitrogen is 0.75 V at 700°C. This is a lower decomposition voltage than that of AlCl_{3(l)}, Al₂S_{3(s)} and Al₂O_{3(s)} at the same temperature. From the thermodynamic point of view, electrolysis has a good potential for extracting aluminum from Al nitride. One of the major challenges is to find the appropriate electrolytes that can dissolve the very stable AlN_(s). Bonomi et al.^[11] carried out a limited study on the solubility and the electrolysis of AlN in molten salt

Table 3 Summary of previous major works/patents in nitride route*

Year	Author	Reactions and parameters	Process details
2008	Joo and Jung	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + \text{CO}$ Temperature: 800–1600°C	The carbothermal reduction and nitridation (CRN) of alumina to Al nitride was investigated in a gas environment consisting of N_2 and CO. The CRN reaction of alumina is slowing with increasing content of CO in the mixed gas
1998	Kotaka <i>et al.</i> ^p (Toshiba Ceramics Co.)	Calcination of $\gamma\text{-Al}_2\text{O}_3$: 300–1100°C Nitridation temperature: 1200–1700°C Gas: mixtures of NH_3 and hydrocarbons Purity: 99%	A method of manufacturing Al nitride by calcining $\gamma\text{-Al}_2\text{O}_3$ in ammonia and hydrocarbon gas to obtain Al nitride having both carbon content and an oxygen content of 1 wt-% of less
1997	Ravenel <i>et al.</i> ^p (ELF Atochem SA)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + \text{CO}$ Temperature: 1450–1500°C Time: 12 h Residual carbon: <700 ppm Oxygen content: <1.1% Flowrate of granule: 4.4 kg h ⁻¹ Flowrate of N_2 : 12 kg h ⁻¹	A continuous process for production of Al nitride by the carbonitriding process of alumina
1996	Ravenel <i>et al.</i> ^p (ELF Atochem SA)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + \text{CO}$ Exchange surface area/volume: 5–50 m ² C/ Al_2O_3 = 3 Granules feedrate: 5 kg h ⁻¹ N_2 feedrate: 20 kg h ⁻¹ Yield: 100% Time: 12 h Temperature: 1350–2000°C	Continuous production of Al nitride by carbonitriding of alumina in a moving bed reactor reaction zone comprising at least one conduit
1993	Dorn <i>et al.</i> ^p (Hoechst)	Calcination of mixture at 400–1000°C Nitridation at 1400–1700°C (1–100 h)	Production of fine Al nitride by reaction between Al hydroxide with carbon in the presence of flowing nitrogen
1992	Dunn <i>et al.</i> ^p (Dow Chemical Co)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + 3\text{CO}$ Temperature: 1650–1750°C Time: 90 min Frequency: 1100 vibration min ⁻¹ Yield: 97 wt-%	Purification of Al nitride produced by carbothermal reaction of Al oxide, carbon and nitrogen. Significant amount of the surface portions are removed by mechanical agitation or mechanical abrasion to leave behind Al nitride pellets having significantly increased purity
1991	Nakano <i>et al.</i> ^p (Sumitomo Chemical Co Ltd)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + 3\text{CO}$ Temperature: 1500–1700°C Time: 2–10 h, starting materials <5 μm O, <2 wt-% Fe, <20 ppm	Production of Al nitride by firing and reacting alumina and carbon mixture in a nitrogen containing atmosphere
1989	Bolt ^p (Du Pont)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + 3\text{CO}$ T nitridation = 1550–1800°C	Production of Al nitride fibers/films through carbontiridation of precursor fibers/films containing source of alumina and carbon
1986	Kuramoto <i>et al.</i> ^p (Tokuyama)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 (\text{NH}_3) = 2\text{AlN} + 3\text{CO}$ Temperature: 1400–1700°C Yield: 94 wt-%	Production of Al nitride fine powder (not more than 2 μm) by firing alumina carbon mixture after optionally drying it
1963	Paris and Perieres ^p (Pechiney)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + 3\text{CO}$ $n\text{Al}_2\text{O}_3 + 3\text{C}_n\text{H}_{2n+2} + n\text{N}_2 = 2n\text{AlN} + 3n\text{CO} + 3(n+1)\text{H}_2\text{CH}_4 + \text{O}_{2+}2\text{N}_2\text{CO} + 2\text{N}_2 + 2\text{H}_2$ $\text{Al}_2\text{O}_3 + 3\text{CH}_4 + \text{N}_2 = 2\text{AlN} + 3\text{CO} + 6\text{H}_2$ Temperature: 1200–1750°C	Manufacturing of Al nitride from the Al ores reacting with nitrogen and a reducing agent (hydrocarbon), which is relatively free of impurities and unreacted components
1962	Clair ^p (Pechiney)	$T = 1750^\circ\text{C}$	Development of reactors for continuous production of Al nitride. Counter current reactor, vertical shaft. A mixture of alumina, carbon and calcium aluminate binder
1961	Perieres and Bollack ^p (Pechiney)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + 3\text{CO}$ $\text{AlN} + \text{C} = \text{AlCN}$ Yield: 99% Temperature: 1700°C (nitridation) 700–800°C (roasting) Time: 2 h Nitrogen flowrate: 100 L min ⁻¹	A process for making Al nitride having a degree of purity above 97%, particularly free from any substantially amounts of alumina or carbon
1918	Shoeld ^p (Armour Fert. Works)	$\text{Al}_2\text{O}_3 + 3\text{C} + \text{N}_2 = 2\text{AlN} + 3\text{CO}$ Temperature: 1800–2000°C Time: 3–4 h	Production of Al nitride from comminuted carbon, alumina, and a binder mixture, and a nitrogen containing gas travelling in opposite directions by passing a heating current of electricity

*^prefers to patent.

(Li_3N – LiCl) bath at 660–700°C. The current efficiency for this system was 83% with a cathodic current density of $\sim 1.5 \text{ A cm}^2$. No further results indicating the successful of the process have been presented. Goto et al.^[38] used the salt system of LiCl – KCl – Li_3N to deposit AlN film onto Al substrate. Figure 6 shows the E– pN^{3-} diagram for the Al–N system in a LiCl – KCl eutectic melt at 450°C showing the region where Al solid is stable. Yan^[138] conducted a direct electrochemical reduction of AlN cathode in a CaCl_2 – NaCl melt at 1133 K and observed a pure Al droplet. The yield, however, was low, i.e. 3–5%.

CONCLUSION

Many researchers have pursued an alternative commercial method for Al production. Although carbothermal reduction of alumina or aluminous ores (direct or indirect) offers the potential for lower energy consumption and improved productivity, compared to existing process, to date, none of the proposed processes have been successfully commercialised in a plant scale. In the case of direct carbothermal reduction of alumina/ aluminous ores, a mixture of Al carbide and metallic Al is formed. Equilibrium studies show that the driving forces for both Al carbide and Al metal formation by carbothermic reduction of alumina are similar, therefore it is difficult to obtain high yield of pure Al. This route has other difficulties, including a high operating temperature and yield problems associated with Al vapour loss and back reactions with carbon monoxide forming Al oxides and carbides. The recent technology in this area has shifted to a multi stage process, the Alcoa-Elkem process, where a slag of Al_2O_3 – Al_4C_3 is first produced followed

by extraction of Al. Alcoa continued the development of the carbothermal process on its own, particularly on the improvement of the off-gas cooling system. They reported a successful test campaigns that run for several weeks, with each tap generates several hundred kilograms of metal with total yield in tonnage scale.

In the case of multistage production of aluminum through the formation of intermediate compounds; there had been intense developments of the chloride route in the 1960s and throughout the 1970s with major players including Alcoa and Toth Al Corporation. At one stage, the Alcoa chloride process (carbochlorination followed by electrolysis) was used to produce Al commercially. This, however, was halted in the mid-1980s due to problems associated with production and handling of pure Al chloride and chlorine at high temperatures.

In the sulphide route, $\text{Al}_2\text{S}_{3(l)}$ can be produced by carbo-sulphidation of alumina or aluminous ores. Al metal can be extracted from $\text{Al}_2\text{S}_{3(l)}$ by disproportionation and electrolysis processes. In the 2000s, Corus developed a process for making Al through carbo-sulphidation followed by electrolysis. This, however, is not yet commercialised.

There is also the nitride route where $\text{AlN}_{(s)}$ is produced from alumina–graphite mixture reacted at 1700°C in nitrogen containing gas. One of the major challenges is to find the economical route to extract Al from $\text{AlN}_{(s)}$. The nitride is a very stable phase but can be dissociated to Al metal at $>2400^\circ\text{C}$ at 0.1 MPa pressure. The theoretical decomposition voltage of Al nitride to Al and nitrogen is 0.75 V at 700°C. It is the lowest compared to the decomposition voltage of $\text{AlCl}_{3(l)}$, $\text{Al}_2\text{S}_{3(s)}$ and $\text{Al}_2\text{O}_{3(s)}$ at the same temperature. Therefore, electrolysis has potential to be used

Fig. 6 Potential– pN^{3-} diagram for Al–N system of LiCl – KCl eutectic melt in presence of 10^{-3} cation fraction of Al^{3+} at 450°C^[38]

for extracting aluminum from Al nitride. However, to date no appropriate electrolytes are available to dissolve the very stable AlN.

In summary, direct carbothermic reduction has yet to be commercialised because of problems with extreme operating conditions and yield, while, two stage indirect carbothermic reduction using Cl, S and N sources to form intermediates have been investigated but still require significant developments. No systematic thermo-dynamic examination of all the options has been published in the literature.

ACKNOWLEDGEMENT

The current study is funded by the 'CSIRO – Breakthrough Technologies for Primary Aluminium' Research Cluster.

Properties of Pure Aluminum

Alexey Sverdlin

Bradley University, Peoria, Illinois, United States

Abstract

The properties of aluminum including: light weight, high strength, and resistance to corrosion make it an ideal material for use in applications such as: transportation, food and beverage packaging, construction, defense and aerospace, machinery and tools and consumer products. In addition to reviewing various grades of aluminum, this article will provide an overview of important properties including: crystal structure, density, thermal expansion, thermal and electrical conductivity, Debye temperature, magnetic susceptibility, electrical properties, compressibility, optical properties, solidification and melting, corrosion, mechanical properties and hydrogen solubility.

Keywords: Corrosion; Hydrogen solubility; Mechanical properties; Physical properties.

INTRODUCTION

Aluminum's unique properties – its light weight, high strength, and resistance to corrosion – make it an ideal material for use in conventional and novel applications. Aluminum has become increasingly important in the production of automobiles and trucks, packaging of food and beverages, construction of buildings, transmission of electricity, development of transportation infrastructures, production of defense and aerospace equipment, manufacture of machinery and tools, and production of durable consumer products. As demand for more technologically complex and ecologically sustainable products increases, opportunities for aluminum will continue to expand.^[1]

Aluminum is the third most abundant element in the Earth's crust. Aluminum is the chemical element of the 3rd group in the periodic table of the elements. The atomic number of aluminum is 13, values for the atomic weight are 26.9815 based on 12C, and 26.98974 based on ¹⁶O.^[2] Aluminum has a silver-white color. It does not have any natural isotopes. Its artificial isotopes are radioactive isotopes – ²⁶Al and ²⁷Al. The isotope ²⁶Al has a half-life of 10⁶ years and isotope ²⁷Al is stable and consists of 14 neutrons and 13 protons. Table 1 lists the properties and characteristics of some isotopes found in aluminum.

The nuclear properties of aluminum are of practical interest. The naturally occurring isotope Al²⁷ has a cross section for thermal neutrons of 0.21 barn (1 barn = 10⁻²⁴ cm²). This low cross section combined with the short half-life of the radioactive product from the irradiation of aluminum an especially attractive material for use within nuclear reactors. In the early nuclear reactors, aluminum was used almost exclusively for protective sheaths around uranium fuel elements and as tube and fittings for conducting coolant through the pile.

Aluminum may possess a coordination number for oxygen of either 4 or 6. The process of recrystallization of aluminum oxide is normally slow. Thus, there are a great many crystal structures for aluminum oxide. The corundum structure has only 6 coordinate Al in hexagonal crystals. It can probably be viewed as a distorted hexagonal closest packed structure of oxide ions, with some of the octahedral holes occupied by Al³⁺ ions. Beta alumina has spinal structure with extra cation vacancies to bring the stoichiometry to M₂O₃ from the ideal spinal formula of MM₂O₄.

GRADES OF ALUMINUM

Depending on amount of impurities, aluminum is classified into extreme purity aluminum and commercial purity aluminum (primary aluminum).

In Russia there are four grades of extreme purity metal with the content of aluminum no less than 99.996%; 99.99%; 99.97%, 99.93%, other elements present are iron, silicon, copper.^[4] The chemical composition of primary aluminum is presented in Table 2 (Russian Standard GOST 11069–74).^[4]

Table 3 shows nomenclature for the various degrees of purity of aluminum accepted in the USA.^[5] Aluminum exceeding 99.99% in purity, produced by the Hoopes^[6] electrolytic process, was first available early in 1920. In 1925, Edwards^[7] reported some of the physical and mechanical properties of this grade of aluminum. Taylor, Willey, Smith, and Edwards^[8] published a paper in 1938 that gave several properties for 99.996% Al that was produced in France by a modified Hoopes process.

Based on ISO standards the classification of aluminum is shown in the Table 4.^[9]

PHYSICAL PROPERTIES

The properties of aluminum depend to some extent on purity. This may vary from the ordinary aluminum of commercial purity to super-purity aluminum. For special purposes, aluminum may be further purified by zone refining to give a purity of about 99.99995%. Aluminum is well known for its low density, 2.7 g/cm³, high reflectivity and high electrical and thermal conductivity. It is very resistant to atmospheric corrosion, due to instantaneous formation of an adherent oxide film, which protects the metal against further attack. The more important physical properties are shown in Table 7, which also indicates how these properties are affected by purity.^[11] It will be seen that the main effects of purity are upon electrical resistivity (the electrical resistance offered by a material to the flow of current, times the cross-sectional area of current flow and per unit length of current path; the reciprocal of the conductivity) and thermal conductivity.

Crystal Structure and Atomic Radius

Aluminum has the face-centered cubic crystal structure over the whole temperature range up to the melting point with the coordination number 12 (each atom had the same number of nearest-neighbor or touching atoms) (Fig. 1).^[12] This crystal structure is the most packed cubic lattice. The closest distance between two atoms in the aluminum structure is 2.863 Δ . The atomic packing factor is 0.74. The accepted lattice constant of aluminum crystal structure a is 4.0414 Δ at room temperature.^[13] The lattice

is stable at the temperatures from 4 K up to a melting point of 933 K.^[14] Measurements of 99.99% Al (corrected for refraction) by Figgins et al.^[15] give $a = 4.04963\Delta$ at 25°C (standard deviation 0.00002 Δ) agreeing very well with the results of Straumanis.^[16]

Atomic radius of aluminum determined as half of the distance between the nearest-neighbors in a crystal structure of a pure element is equal to 1.43 Δ .^[17–19] There is the metallic bonding in aluminum crystal structure. The atomic weight of aluminum is 26.9815 (on carbon¹²C) and 26.98974 (on oxygen¹⁶O).^[20]

The equilibrium interatomic distance at metallic bonding corresponds to strong overlapping of the external electron shells. Therefore, the atomic radius is equal approximately to the orbital radius of external shells.

The ionic radii describe more precisely the interatomic distance. The ionic radius of aluminum is 0.53 Δ that is calculated based on the distribution of the density of electrons.^[19] The interatomic distance in the aluminum crystal structure can be described by a system of atomic-ionic radii. This distance is defined by an orbital radius of a free atom and equals 1.23 Δ .

Defects of a Crystal Lattice

Vacancies are the simplest point defects in a crystal lattice. It is a normally occupied lattice site from which an atom or ion is missing. The ability of a crystal to keep point defects, formed in one way or another depends on their mobility in a crystal.

One way that determines the vacancy concentration, is the measurement of the length of a specimen and the period of a lattice during heating to a given temperature: $G_v = 3 (\Delta L/L - \Delta a/a)$, where $\Delta L/L$ -change in length of a specimen at some instant, $\Delta a/a$ -change in the period of a

Fig. 1 The crystal structure of aluminum – the face-centered cubic crystal structure: (a) a hard sphere unit cell representation, (b) a reduced-sphere unit cell, and (c) an aggregated of many atoms^[85,86]

lattice at the same instant. The equilibrium concentration of vacancies in pure aluminum at the temperature close to the melting point using this formula is 9.4×10^4 .^[21,22] The energy of formation ($\bar{A}_f$) and migration ($\bar{A}_m$) vacancies and also the energy of activation for self-diffusion (E_{sd}) of vacancies in aluminum are shown in Table 8:^[21]

The equilibrium concentration of vacancies at any temperature can be determined by the formula: $n = e^{-E_s/KT}$. The vacancies will make an impact on electrical resistivity of the metal. The most sensitive to their presence is electrical resistivity. For aluminum the value of electrical resistivity caused by vacancies and interstitial atoms is $3.4 \mu\Omega \times \text{cm}/\text{at}\%$.^[23,24]

Supersaturation of the metal by vacancies will make an impact on its mechanical properties. The critical shear stress for the quenched crystals of aluminum is approximately five times higher than for annealed crystals. Dislocations are the linear crystalline defects around which there is atomic misalignment. Plastic deformation corresponds to the motion of dislocations in response to an applied shear stress. Edge, screw, and mixed dislocations are possible.^[22–24]

Slip occurs on the most densely packed crystallographic planes and, in those planes, along directions having the greatest atomic packing (the slip plane is the crystallographic plane along which the dislocation line). For metals with FCC crystal structure including aluminum, the slip directions are $\langle 110 \rangle$ -type because the shortest vector of a lattice is equal 1/2 of the direction $\langle 110 \rangle$. For this crystal structure, the slip planes are $\{111\}$ -type. The magnitude and direction of the lattice distortion associated with a dislocation is expressed in terms of a Burger vector.

Table 8 Energy of formation, migration and self-diffusion of vacancies in aluminum

Defect	E_f , eV	E_m , eV	E_{sd} , eV
V_1	0.76	0.65	1.4
V_2	$E_b=0.17$	0.50	–

V_1 = single vacancy (a vacancy which has no other vacancy in its nearest proximity).
 V_2 = two-vacancy (a pair of two vacancies lying close to one another).
 $\bar{A}_b$ – the bonding energy of two-vacancies.

The splitting width of a dislocation is determined by the packing defect energy between the atoms. The greater the packing defect energy, the less the partial dislocations are diverged. For aluminum this value is very high and equals 135 ergs/cm^{-2} .^[22]

Several slip systems may exist for a particular crystal structure. The number of independent slip systems represents the different possible combinations of slip planes and directions. For aluminum with FCC crystal structure, there are 12 slip systems: four unique $\{111\}$ planes and, within each plane, three independent $\langle 110 \rangle$ directions.

The critical stress σ required for noticeable rate of the dislocation nucleus formation can be represented by the relationship σ/G , where G is the shear modulus. Table 9 shows this relationship for aluminum.

Density

The theoretical density of aluminum calculated on the translation period of the lattice (the minimum distance

over which a unit cell must be successively translated in any of the directions peculiar to a given crystal system, in order to create a crystal lattice) is equal 2.69872 g/cm^3 .^[25] Perryman^[26] has found that density of aluminum is $2.6984 \pm 3 \text{ g/cm}^3$ at 20°C as the mean of 12 determinations. The experimental values of for a polycrystalline material are in the limits from 2.6966 to 2.6988 g/cm^3 and for monocrystals are on 0.34% is higher. The density of the molten aluminum with purity 99.996% is shown in Fig. 2.^[27]

The density the solid and molten aluminum is reduced in accordance with increasing of its purity.^[4,28] Figure 3 shows value of density of aluminum depending on purity and the temperature.

Fig. 6 Average coefficient of linear expansion of extreme-purity aluminum from 20°C to temperature t ^[11]

to 500°C. Figure 6 represents the average coefficients of thermal expansion for pure aluminum received by Willey who developed three equations that are useful in calculating linear expansion over three temperature ranges:^[30]

$$L_t(-60 \text{ to } 100^\circ\text{C}) = L_0 [1 + C(22.17t + 0.012t^2)10^{-6}] \quad (1)$$

$$L_t(0 \text{ to } -200^\circ\text{C}) = L_0 [1 + C(21.57t + 0.00443t^2 - 0.000124t^3)10^{-6}] \quad (2)$$

$$L_t(0 \text{ to } 500^\circ\text{C}) = L_0 [1 + C(22.34t + 0.00997t^2)10^{-6}] \quad (3)$$

Where L_0 is length at 0°F, L_t is length at temperature t , °F, within the range indicated, and C is alloy constant that equal to 1.0 for pure aluminum.

Thermal Conductivity

Aluminum, having excellent electrical conductivity, is also a good conductor of heat. Electrical conductivity of metals, as well as thermal conductivity, is governed by behavior valence (external) electrons. On data,^[29] thermal conductivity of aluminum at room temperature (293 K) is 50 cal/cm²/sec/cm/°C.

Figure 7 shows the low-temperature thermal conductivity of a single crystal of 99.996 Al. Some values for the thermal conductivity of aluminum from 20°C (68°F) to the melting point of 660°C (1220°F) have been reported.

The best data is obtained by calculating the thermal conductivity from room-temperature electrical-conductivity data, using one of these equations:

Thermal conductivity values for pure aluminum calculated from the following equations:

$$K = 4.65\lambda T \times 10^{-9} + 0.05 \quad [36]$$

$$K = 5.02\lambda T \times 10^{-9} + 0.03 \quad [37]$$

$$K = 5.3\lambda T \times 10^{-9} + 0.025 \quad [38]$$

$$K = 4.9\lambda T \times 10^{-9} + 1.2T \times 10^{-4} \quad [39]$$

Thermal conductivity values for pure aluminum calculated from each of these equations are shown in Table 11.

Figure 8 (top) shows the thermal conductivity from 0 to 900°C; (bottom) from 0 to -273°C.^[35]

However, thermal conductivity is not completely dependent on the behavior of electrons. Inasmuch as the thermal energy of a crystal, above all the energy of the atom vibration near to their equilibrium interstitial positions of a lattice, the energy can be spread from a point to a point at the expense of interaction of atoms with each other. The vibrations of a lattice are described by sound waves propagation, named phonons.^[18] According to this definition the total thermal conductivity k_t is the sum of the two contributions, or

$$k = k_p + k_e$$

where k_p and k_e represent the lattice vibration and electron thermal conductivity, respectively. For metals having good thermal conductivity at room temperature k_t is

Fig. 7 Thermal conductivity of 99.996 aluminum at low-temperature^[35]

Table 11 Thermal conductivity of pure aluminum

Temperature, °C	Cal/cm ² /s/cm/°C				Average

600	0.49	0.50	0.52	0.56	0.52

Fig. 8 Thermal conductivity of super-purity aluminum from 0 to 900°C (top). Thermal conductivity of extreme-purity aluminum from 0 to -273°C (bottom)

10–100 cal/cm²/sec/cm/°C. In metals electron thermal conductivity prevails and the value k_f is close to 1.

The thermal conductivity k is impossible to consider as a linear function of the temperature.^[18] The results of experiments^[36,39] show it clearly. For aluminum the value k in the interval of temperatures from 120 to 700 K changes less than on 50%, whereas the electrical conductivity in the same interval of temperatures changes on 1300%.

At elevated temperatures the aluminum thermal conductivity depends on purity of the metal and increases with the higher purity. For commercial aluminum (99.49% and 99.70% Al) the thermal conductivity at 200° is 209 and 222 Bt/m-K, respectively. For electrolytic refined aluminum with purity 99.9% at 190°C thermal conductivity increases up to 343 Bt/m-K. The impurities, such as Cu, Mg, and Mn in aluminum reduce the thermal conductivity. For example, the addition of 2% Mn reduces the thermal conductivity from 209 to 126 Bt/m-K.^[40]

At the temperatures >100 K, the true thermal conductivity of completely annealed aluminum with the extreme purity (99.99%) is not sensitive to the degree of purity. At elevated temperatures, sensitivity to purity of a material, controllable by electrical resistivity, is displayed.^[41]

Debye Temperature

Debye temperature is the temperature, characteristic for a given substance, at which the whole spectrum of frequencies of atomic vibrations in the crystal lattice becomes narrowed close to its upper limit. The thermal atomic vibrations of the lattice are qualitatively defined in two temperature areas, determined by a ratio between the energy of thermal vibrations of atom and the bonding energy between atoms in a solid state.

In the first area for temporary intervals $t < 10^{-13}$ sec the lattice is not a periodic structure. The atoms are shifted about their equilibrium position. However, for $t \gg 10^{-13}$ sec a balance of atoms positions occurs. Periodicity of a lattice is displayed. It reflects the periodicity of balance arrangement of the separate atoms.

At low temperatures the bonding energy of atoms is so great in comparison with the energy of vibrations that an atom at the displacement from the balance position in some direction entraps the adjacent atoms in the same direction. There is the coordinated displacement of atoms.^[18,42]

Debye temperature defines the temperature at which it is necessary to carry out annealing of a monocrystal for residual stress removal. Annealing at a temperature close to $T_m > T_D$ does not improve but worsens a crystal lattice as it results in occurrence of vacancies, interstitial atoms, etc.

Annealing at the temperatures $T_m < T_D$ thermal vibrations cannot not remove residual stresses of a lattice. For pure aluminum this temperature is 375 K.^[18]

Magnetic Susceptibility

The magnetic permeability of a substance is given by $\mu = 1 + 4\pi K$, where K is the magnetic susceptibility. If the susceptibility is positive, the material is “para-magnetic” and the permeability is greater than unity. Paramagnetism is a property characterizing materials that have a permanent magnetic moment. Because aluminum has an odd number of valence electrons (3), it is paramagnetic. Its magnetic susceptibility depends on the temperature.^[43] Figure 9 shows the dependence of magnetic susceptibility on the temperature and purity of.^[43]

Fig. 9 Magnetic susceptibility of aluminum as a function of temperature and purity^[43]

Sleepy^[44] showed that for unalloyed aluminum containing small amounts of impurities, the effect of strain sensitivity on magnetic susceptibility is negligible (99.999% Al – 0.6276×10^{-6} per gram; 99.99% Al – 0.6267×10^{-6} per gram). Alloying of aluminum with the small additives Fe, Mn increases its magnetic susceptibility slightly. An introduction of other alloying elements decreases this tendency to its reduction.^[25] The deformation also promotes decreasing of magnetic susceptibility: at 50%> deformation of aluminum this characteristic has decreased on 5–15%.^[25,43,45,46]

Transverse Magneto-Resistance

Because refrigeration of the conductor of an electromagnet can result in overall power savings through reduction in the resistivity of the conductor, data on the magneto-resistance are necessary. The use of aluminum in a high-field magnet is advantageous because its magneto-resistance tends to saturate at a low value. Figure 10^[47] shows the magneto-resistance of 99.9983 and 99.999 Al. These data indicate that the magneto-resistance of both aluminum specimens at 20 K approaches saturation at approximately 20 kgauss.

Electrical Properties

Electrical resistance can be measured by the resistance-ratio test. This test is a very sensitive qualitative method

of measuring purity of 99.999% and higher. The resistance of electrons through a sample of high-purity metal, particularly at low temperatures, is extremely sensitive to the amount of trace elements present in the sample.

Gauthier^[48] showed that a volume conductivity for 99.997 Al of 65.45% (a resistivity of $2.6434 \mu\Omega\text{-cm}$) at 20°C. Taylor's results of the volume resistivity are $2.6548 \mu\Omega\text{-cm}$ (the volume conductivity is 64.94%)^[32] for 99.996 Al at the same temperature. Babilon^[49] determined that the volume resistivity of 99.993 Al is $2.6484 \mu\Omega\text{-cm}$ (the volume conductivity is 65.1%)

Wiley^[8] determined that Matthiessen's law holds for high-purity aluminum from 0 to 300°C, and the term $0.0115 \mu\Omega\text{-cm}/^\circ\text{C}$ may be used to determine the resistivity of pure aluminum over this temperature range. Pochapshky confirmed that statement with his results (Fig. 13).^[50]

The results of the resistivity of molten aluminum are presented in Fig. 12^[51] and Fig. 13 shows the resistivity from 0 to 1200°C.

As the purity of aluminum increases, the electrical resistivity at low temperature decreases. At the boiling point of liquid helium, 4.2 K, very small changes in metal purity cause large changes in resistivity, contrary to the elevated temperature behavior (Fig. 14).^[52]

Aluminum exhibits superconductivity near absolute zero. Although values for the superconducting transition temperature for 1.14–1.97 K have been reported, data or Satterthwaite^[53] show the best value for the transition temperature to be 1.187 K.

Electrical Conductivity

Aluminum, relating to the trivalent metals, is a good conductor. The electron's behavior in aluminum is similar to the behavior of free electrons. Electrical resistivity of extreme purity aluminum (99.990%) at room temperature is $2.65498 \times 10^{-8} \Omega\text{m}$ or 64.94% of electrical resistivity annealed copper based on the international standard.^[24,41]

The grain size affects slightly on electrical resistivity of aluminum but its electrical conductivity after strain hardening in a direction of deformation grows by 0.5–1.0%.^[32]

Electrical conductivity of aluminum strongly depends on a nature and quantity of impurities present. According to I. N. Fridlyander^[4] impurities having increasingly negative influence on electrical conductivity can be arranged in the following order: Cr, V, Mn, Ti, Mg, Ag, Cu, Zn, Si, Fe, Ni.

The main impurities in aluminum are Si, Fe, Cu, Zn, and Ti. At the contents of Si up to 0.006% the value the ratio Fe/Si (from 0.8 up to 3.8) affects slightly the electrical resistivity. But the increasing of the Si content up to 0.15–0.16% will change the picture. This ratio will affect drastically. Table 12 shows the character of this influence.

Impurities such as Cr, V, Mn, Ti influence most negatively on electrical resistivity of aluminum. Therefore in aluminum, intended for an electrical industry, the total amount of Cr+V+Mn+Ti should not exceed 0.015% and even 0.01% with the content of silicon accordingly 0.12 and 0.16%.

The specific electrical resistance of aluminum of commercial purity increases 164% at the transition from a solid condition into liquid: $\rho_s = 1.65 \times 10^{-8} \Omega\text{m}$; $\rho_l = 27.1 \times 10^{-8} \Omega\text{m}$ (Figs. 13 and 14). For 99.99% purity aluminum $\rho_s = 10.8 \times 10^{-8} \Omega\text{m}$; $\rho_l = 26.6 \times 10^{-8} \Omega\text{m}$.

At temperatures close to the absolute zero aluminum has superconductivity.^[25]

Compressibility

Using a reflected light technique, Doran, Fowles, and Peterson measured the compressibility of aluminum at pressures between 10 and 130 kilobars. Their results (Fig. 15) showed the good agreement with the data received by Bridgman.^[55,56]

Results of Doran and et al. that are presented in Fig. 16^[57] found an excellent correlation with other researchers.

Optical Properties

The optical properties of a metal are characterized by the index of refraction, n , and the extinction coefficient, k .

Scientists from the United States Army Engineering Research and Development Laboratory and the U.S. Naval Research Laboratory determined the optical properties of evaporated aluminum films. Their results are presented in Tables 12, 13 and Fig. 17.

Spectral Reflectance

The reflectivity of smooth aluminum surfaces to light is more than 90% for wavelengths from 0.9 to 12 μm .^[25] At wavelengths below 0.2 μm , at which wavelength the reflectivity of smooth aluminum surfaces are about 70%. Bennett, Silver, and Ashley^[60] investigated the reflectance of 99.999 Al. Their results are presented in Figs. 18 and 19.

Highest reflectivity is obtained by vapor deposition, which can produce very smooth surfaces. Vapor-deposited films require a minimum thickness of about 10^{-5}cm for maximum reflection. The reflecting poser of an aluminum surface decreases with roughness. A sandblasted aluminum surface may exhibit only 15–25% of the reflectivity of a polished surface of metal of the same composition. Figure 19^[46] presents the normal spectral reflectance for various pure aluminum surfaces from brightened aluminum to aluminum

having a clear oxide coating. Although most clear anodic coatings a few tenths of a mil thick reduce the reflectance of 99.99 Al only to 80%, they have much greater effect on the emissivity, depending upon the electrolyte in which the anodic coating is formed.

Emissivity of polished aluminum at room temperature is only several percent of that of a blackbody.^[25] Rough finishes may raise the emissivity to about 20–30%. Emissivity increases with temperature to reach values of 15–20% for the liquid state. Figure 9 shows the relation between oxide film thickness and emissivity at 100°F for anodized films formed in different electrolyses.^[61]

The emissivity of aluminum at 4 K (–452°F) and 76 K (–322.6°F) is 1.1% and 1.8% respectively. Goldsmith, Waterman and Hirschhorn^[62] showed that aluminum heated to 600°C might have emissivity as low as 6%. Moeller and Miething^[63] showed that the emissivity of molten aluminum to be 12% at 700°C and 17% at 1000°C.

Solidification and Melting

Solidification of liquid aluminum begins at 660.37°C.^[25] The process of solidification of the liquid metal usually

begins at separate points. In a volume of the metal they located chaotically. The arrangement of atoms in the small volumes of the melt is similar to their arrangement in a crystal lattice.^[17] In particular, the coordination numbers of the first sphere are found. The essential distinction lies in the fact that the mobility of atoms in a liquid state much more than in solid one. In a molten metal there are the separate areas both with smaller, and with larger coordination numbers. In a certain moment there are the areas with the coordination number similar to a solid crystal. In aluminum this number is equal to 12. The stability of such an area depends on their size. Under certain conditions they can become a nucleus of crystallization. In other words, if the size of a nucleus is less than the critical radius r_k , there will occur its spontaneous disintegration. If the size of a nucleus is larger than r_k growth will take place. The value of r_k , at which nucleus is growing, should be about 10 atomic diameters. Aluminum has an atomic diameter is 2.86Δ so the size of a nucleus should be equal or exceed the value 2.86Δ .^[17] Table 14 shows the coordination numbers in the melt and the crystal of aluminum.^[17]

Melting of aluminum with purity of 99.996% occurs at the temperature of 933.4°C.^[18] At the melting point there is a step change of many properties of the metal such as density, electrical resistivity, deformability, and others (Table 15).

Table 16 Relationship between the purity of aluminum and its melting point

Degree of purity, %	99.2	99.5
The melting point, °C	657	658

Above the melting temperature the crystal lattice can remain “mechanically” stable. In aluminum an interval overheating (stability of a lattice) is up to 5°C. The melting point depends on purity of aluminum.^[4,64] Table 16 shows the relationship between the purity of aluminum and its melting point.

The specific heat of melting for pure aluminum is $2.56 \pm 0.05 \text{ kkal} \times \text{mol}$ ($397 \text{ J} \times \text{g}^{-1}$).^[65] The melting temperature grows with increasing of pressure. Figure 20 represents the change of the melting temperature at normal pressure depending on applied pressure. It is expressed by a derivative of dT_{mp} with respect to dP , 10^{-2} °C/MPa ($dT_{mp}/dP = 6.41$).^[66]

CORROSION PROPERTIES

Corrosion is one of the main reasons for failure of the engineering materials in service. Pure aluminum resists corrosion better than commercial one. That is why it is used for cladding alloys. Aluminum has a resistance to corrosion

Fig. 20 Relationship between the melting point of aluminum and the applied pressure

in some common environments, including the ambient atmosphere. It has been associated with the presence a continuous oxide film on its surface.^[67] The standard electrode potential of aluminum is less than the majority of aluminum alloys. Therefore protecting aluminum by forming a protecting cathodic layer. In air at the room temperature this film on a surface of aluminum will be formed in 10^{-4} sec.^[68] This film prevents further deterioration of the metal. Its thickness in usual conditions is 5–20 nm. The molecule volume of the oxide is almost in 1.3 times more than volume of aluminum participating in the oxidation reaction. The thickness of a film is increased in presence the water vapor. At the elevated temperatures the film has the complex structure.

A role of a protective film on a surface of aluminum reflects specificity of its behavior but do not explain its interaction with various environments (Figs. 21 and 22).^[69] Aluminum and its alloys are sensitive to various kinds of local corrosion under the stressed and unstressed conditions.

The following are lists of chemicals where there is considerable resistance to corrosion (Table 17) and where aluminum has poor corrosion resistance (Table 18).^[70]

The standard electrode potential of aluminum (value of the equilibrium reversible potential at activity of ions of aluminum equal 1.0) is 1.663 V with respect to the normal hydrogen electrode.^[68,71] Therefore, in “the order of voltage” aluminum is located in more negative area than Cu, Cr, and Fe. This metal is increasingly active.

From the diagram it is worth noting that aluminum having rather negative values of electrode potential should not be destroyed in water, i.e. it is in the field of immunity in the form of a neutral material. However, as a result of reduction of water there is a process of increasing of alkalinity of the electrolyte. This shifts into the area of solubility aluminate-ions in water.^[72]

Dissolving of compact aluminum in sour solutions proceeds on reaction:

According to this reaction equilibrium electrode potential:^[35]

$$\varphi_p = -1.663 + 0.0197$$

Electrode potentials of allocation of hydrogen and oxygen:

$$\varphi_{\text{O}_2} = 1.23 - 0.059\text{pH} + 0.0141\lg P_{\text{O}_2},$$

$$\varphi_{\text{H}_2} = -0.059\text{pH} - 0.0295\lg P_{\text{H}_2}$$

Aluminum electrodes are highly irreversible in aqueous solutions containing aluminum ions.^[3] Measured potentials of aluminum in highly basic solutions, such as aqueous sodium hydroxide, are anodic to those measured in acid solutions, as would be predicted by the Nernst equation. Figure 22^[73] illustrates the solution potential of 99.999 Al in a 4% NaCl solution as pH varies from 1 to 11.

1M NH ₄ OH	-1.43	-0.80	-1.50	-0.18	-0.53

Table 19 shows that the potential of high-purity aluminum varies considerably in different types of electrolytes, as does that of several other pure metals. In most electrolytes, aluminum is cathodic to magnesium and zinc and anodic to iron and copper.^[5]

The transition from area of solubility of trivalent ions of aluminum into passive area according to the diagram of electrochemical balance corresponds to formation of aluminum oxide from a liquid phase. At normal conditions in water at temperature not higher than 60°C amorphous hydrated aluminum oxide Al(OH)₃ will be formed on a surface in passive area.^[68] At the same temperatures crystal trihydrate of aluminum bayerite-oxide with a monoclinic lattice will be formed. According to^[74] under normal conditions the aluminum oxide film is formed. The first layer with the thickness no more than 10 nm

consists of the amorphous aluminum oxide. The second layer is composite and consists of bayerite and bemite with an orthorhombic crystal lattice. The thickness of a layer depends on the character of environment and the duration of endurance. At temperatures 60–80°C and high a monohydrate oxide-boehmite will be formed on the surface of aluminum.

The most stable form of oxide is hydrargillite (gibbsite), which is trihydrate as well as bayerite but has the different crystal lattice. Hydrargillite (gibbsite) will not be practically formed on a surface of aluminum. As at elevated temperatures on the surface of aluminum boehmite is formed so it is possible to consider that the corrosion resistance in real water environments will be characterized by the diagram constructed for boehmite. The formation of oxide from the state occurs according to the reaction:

The formula calculated for this reaction can be presented as:

$$\text{pH} = 2.67 - 0.33 \lg a_{\text{Al}^{3+}}$$

From the formula it is apparent that at activity $a_{\text{Al}^{3+}} = 1$ pH value is 2.67. At this pH, a transition into the passive region occurs. At decreasing activity, the boundary of absolute value of hydrogen electrode grows. For the normal atmospheric conditions it is possible to accept activity close to 10^{-6} .

Solution of boehmite in alkaline area is defined by the reaction:

The arrangement of the boundary ordinates on the diagram determined by the equation:

$$\text{pH} = 12.3 - \lg a_{\text{AlO}_2^-}$$

The meanings of the hydrogen parameter will depend on the activity:

$$\text{pH} = 12.3 \text{ at } a_{\text{AlO}_2^-} = 1 \text{ and } \text{pH} = 6.3 \text{ at } a_{\text{AlO}_2^-} = 10^{-6}$$

In passive area boehmite can be formed by the direct oxidation of compact aluminum:

In alkaline environments aluminum as well as oxides are dissolved with formation of aluminate-ions:

The calculated equation: $\Omega = -1.26 + 0.0197 \lg a_{\text{AlO}_2^-} - 0.0788 \text{ pH}$.

It defines an arrangement of a series of inclines on the diagram at various values of aluminate-ions activity. These inclines divide areas of insolubility and solubility of aluminates. On the diagram there is the vertical line at $\text{pH} = 5.07$. It is a border of existence Al^{3+} and AlO_2^- . The location of this line on the diagram is calculated from the conditions of the floating balance:

$$\lg \left[\frac{\text{AlO}_2^-}{\text{Al}^{3+}} \right] = -20.30 + 4\text{pH}$$

The diagrams of electrochemical balance establish the corrosion conditions of aluminum and its alloys in the plain water environments. They can be used at development of the optimum parameters for some processes.

There is the opportunity of "disruption" the oxide film on a surface of aluminum. It is associated with the formation in a barrier layer of narrow channels with increased ionic conductivity.^[72] It is achieved at a certain energy level of a surface. The absorption of certain anions, first of all halide anions, lowers the level of energy necessary for displaying of this effect.

Increased corrosion or disruption of the oxide film a consequence of introduction into a film of certain elements at alloying of the metal.^[75] For example, the introduction of tin into a film increases its ionic conductivity. It increases the rate of solution of aluminum.

Pitting is the most common form of very localized corrosion attack in aluminum in which small pits or

holes form. The disruption of the oxide film causes this form of corrosion. Thus the significant part of a surface is in a passive condition. The formation of the pits themselves is strongly accelerated by the addition of oxidizers. It especially occurs in solutions containing chloride and phosphate ions. The oxidizers exert the greater influence in acid environments than in alkaline. The most effective oxidizers are hydrogen peroxide and free chlorine (chlorinated water or calcium hypochlorite and to a smaller degree are sodium chlorate and nitric acid). In the formed pit, dissolution of the metal occurs intensively. The meaning of corrosion potential depends on purity of the metal. The literature indicates^[72] that the probability of occurrence of corrosion pits decreases on aluminum with purity of 99.99%.

The corrosion resistance of electrolytic purified (refined) aluminum (99.99% Al) in 3–15 times is higher than for commercial purity aluminum. The corrosion rate of aluminum of various purity characterized by weight losses or volume of hydrogen escaping from the surface unit in 5% HCl solution is shown in Fig. 23.

For aluminum with purity 99.99% and higher the rate of corrosion mainly depends on the copper content. So an aluminum sheet (copper content higher than $2 \times 10^{-3}\%$), with thickness of 1.5 mm, in 20% HCl acid during 1 week corroded completely through; in the same conditions aluminum with $0.9 - 3 \times 10^{-4}\%$ Cu completely corroded through after two weeks only. The corrosion resistance of aluminum decreases with the Fe content. Aluminum with the Fe content no more than 0.003% corrodes with the rate of 0.10–0.157 g/(m²×h).

Titanium does not have appreciable influence to corrosion resistance of aluminum in 5% HCl solution. Beryllium (Be) in amount of 0.05–0.5% reduces slightly corrosion resistance of aluminum of commercial purity. At addition of 0.14–0.19% Nb reduces the corrosion resistance considerably.

The small additives of Gallium and Rhenium negatively influence on corrosion resistance. For aluminum A7 containing 0.5% Ga, the rate of corrosion reaches 120 g/m²×h. For aluminum containing 0.3% Re the rate is 250 g/m²×h.^[4]

Aluminum is not resistant to corrosion in many mineral acids, except for acids with strong oxidizing properties. But the action of such acids depends on their concentration: diluted HNO₃ is rather aggressive environment for aluminum, but after achievement of the concentration of 80% the rate of solution does not exceed 0.1 mm/year.^[76] The acid at concentration more than 98% is not active in relation to aluminum. In diluted H₂SO₄ (from 1% up to 20%) all grades aluminum including high purity, have low resistance to corrosion even at room temperature.

Hydrogen halide acids react with aluminum and they are not used in contact with aluminum and its alloys. In organic acids the aluminum is destroyed very slowly, with the exception of formic acid, oxalic acid and some

Fig. 23 Weight losses and the hydrogen content in aluminum of various purity. (1) Mass loss, g, m²·h; (2) Hydrogen content, l, m²·h

chlorine-containing acids. Glacial acetic acid does not have an appreciable effect on aluminum but the rate of corrosion grows at low concentrations.

The alkalis are usually aggressive in relation to aluminum. At the same time aluminum is resistant to ammonium hydroxide even at pH13. Such salts as chromates, bichromates, silicate, and borates have appreciable inhibiting action and can be used for the protection of aluminum against corrosion in water systems with a closed cycle.

Aluminum has very high resistance in relation to concentrated hydrogen peroxide. It is characterized by good resistance to many organic compounds including acetaldehyde, formaldehyde, and tetrachloride glycerin and also has good resistance to petroleum products.^[76,77]

MECHANICAL PROPERTIES

The mechanical properties of aluminum depend not only upon purity and applied heat treatment. The influence of purity is shown in Fig. 24.^[11] Figure 25 shows the effect of purity on strength and hardness of unalloyed aluminum and Fig. 26 typical tensile properties of alloy 1199 (99.9 wt% Al).

The elastic properties for extremely pure aluminum are: $E=69\text{--}72\text{ GPa}$, $G=25\text{--}26.5\text{ GPa}$, $\nu=0.31$.^[54] Figures 27–29 show mechanical properties of aluminum at various temperatures and applied cold work.

Figure 30 shows relationship between mechanical properties of commercial aluminum and cold work applied. ($E=70\text{--}72.5\text{ GPa}$; $G=27\text{--}28\text{ GPa}$; ($\nu=0.31\text{--}0.33$ (for thin clad sheets $E=68.5\text{--}70\text{ GPa}$)).^[78]

The mechanical properties of pure aluminum, as well as other metals, depend on the temperature of the test. Mechanical properties such as resistance to plastic deformation (tensile strength, yield strength), resistance to the penetration (hardness), as well as impact are the most sensitive to the temperature. The elastic properties of metals and alloys change with the temperature in a smaller degree. The mechanical properties of aluminum at low temperatures and elevated temperatures are shown in Figs. 29 and 31.

Pure aluminum is a non-heat-treatable alloy. There are the various grades of pure aluminum in which the strength is developed largely by strain hardening from the basic annealed temper. A high grade of pure aluminum that became available early in this century was utilized for electrical conductors. This wrought material is known as EC (electrical conductor) metal, has a minimum aluminum content of 99.45%. Pure aluminum of this grade is also used for foil and is designated 1145 alloy. The various grades of pure aluminum used commercially have distinctly higher strength in the annealed condition, and stable properties are developed in the various strain-hardened tempers (Table 20).

Hardness of aluminum as function of purity is shown in Fig. 32.

Fatigue is a form of failure that occurs in structures subjected to dynamic and fluctuating stresses. There is a limiting stress level called the fatigue limit. The fatigue limit is the maximum stress amplitude level below which a material can endure an essentially infinite number of stress cycles and not fail. Most nonferrous alloys such as aluminum, copper, magnesium, do not have a fatigue limit,

Fig. 24 Mechanical properties of annealed aluminum of various purities.^[11] (1) Tensile strength, t/in²; (2) Brinell hardness

Fig. 25 Effect of purity on strength and hardness of unalloyed aluminum

in that the S-N curve continues its downward trend at increasingly greater N values (where S is stress amplitude and N is the number of cycles to fatigue failure).

The fatigue behaviors may be classified into two domains. One is associated with relatively high loads that produce not only elastic strain but also some plastic strain during each cycle. Consequently, fatigue lives are relatively

short; this domain is termed low-cycle fatigue (frequency $f=0.1-5$ hertz) and occurs at less than about $N=10^4-10^5$ cycles. For lower stress levels wherein deformations are totally elastic, longer lives result. This is called high-cycle fatigue (frequency $f=20-50$ hertz) inasmuch as relatively large numbers of cycles are required to produce fatigue failure $N=10^7$ cycles.^[79]

**Fig. 32** Hardness and strength of aluminum as functions of purity

Damage or fatigue failure at high-cycle area occurs basically at elastic and in low-cycle area at elastic-plastic deformation. The endurance characteristics depend on the shape and size of a specimen but also types and frequency of loading. Resistance to fatigue decreases with

increasing load frequency and increasing the absolute sizes of a specimen. The endurance of metals depends on a surface finish. It has been observed that fatigue life is especially sensitive to the condition and configuration of the component surface. Improving the surface finish

Table 21 Results of fatigue test of commercial purity aluminum

Semi-product, heat treatment	a_b , MPa	σ_{-1} , MPa
Sheet, annealed	80	35
Sheet, strain hardening	150	50

by polishing will enhance fatigue life significantly. Like all other metals, when subjected to repeated loading aluminum alloys will fail by fatigue at a lower stress than they can withstand when loaded statically. For a rough estimation of the endurance limits for aluminum is possible to use the following ratio: an endurance limit at tension-compression ($\sigma_{-1}' = (0.85-0.95)\sigma_{-1}$; at torsion $\tau_{-1} = (0.55-0.65)\sigma_{-1}$. The endurance limit of commercial purity aluminum at axial (tension-compression), (flexural) bending loading on the basis of 2×10^7 cycles depends on preliminary heat treating. Table 21 shows the results of this test.^[78]

The Failure Characteristics

Unlike steel specimens, the impact test with a notch for aluminum and its alloys does not have a great deal of importance because aluminum and its alloys do not have a sharp ductile-to-brittle transition temperature. Aluminum having FCC crystal structure remain ductile even at extremely low temperatures;^[4]

To determine the characteristics of failure of aluminum and its alloys at different conditions. The test can be applied. The determined energy of crack propagation is the total energy required for the crack propagation referring to the final cross-sectional area of a specimen. Compared to the meanings of impact tests, the cracking energy is the best combination of toughness with ductility that characterized the resistance of a material to the crack propagation in a field of the elastic deformation. The tear test can be applied to aluminum and its alloys despite their high ductility.

The specifics of the crack initiation at the failure of aluminum of the grade A99 containing no more than 0.01% of an impurity is described in.^[80] The failure of the majority of pure metals under tension is preceded by the necking. The voids occur which link and form the crack. These cracks result the specimen's failure. The characteristics of pure aluminum are the necking process, which is not followed by the porosity formation. The cracks are initiated and propagate in the planes of intensive deformation.

At the room temperature crack are not observed in pure aluminum until close to specimen failure. The irregularity the crystal orientation of in polycrystalline aluminum creates inhomogeneity of the deformation. Increasing the temperature up to 300°C does not show the micro crack initiation up to the deformation of 50–70%. At the elevated temperatures a deformation proceeds also non-uniformly: alongside with the areas having local tension

deformation of about 7–8% are observed areas with compression up to 5–8%.

At 20°C areas with increased and lowered local deformation are not rearranged. These areas are the centers of the sensitivity to damage. Rearrangement occurs at elevated temperatures above 300°C.

In this case the centers of the sensitivity to damage will be formed at the later stage of deformation. So, at the temperature of 300°C the localization of deformation in the separate micro centers is found out at $\epsilon > 10-15\%$, whereas at 20°C $\epsilon < 1-2\%$. Therefore, at room temperature the centers of failure will be formed at initial stages of deformation at elevated temperatures, but at later stages (deformation more than 10–15%). Submicroscopic cracks initiate inside grains at location of crossing slip planes. The average deformation at which their initiation begins grows with increase of the temperature. In all investigated cases, the failure is transcrystalline.

HYDROGEN SOLUBILITY IN ALUMINUM

With nitrogen aluminum creates an aluminum nitrate AlN at 700°C. The reaction is very intensive at 830°C. Aluminum nitrite hydrolyzes easily in the presence of water in the following reaction.

But hydrogen is the only gas to be soluble in both solid and molten aluminum. Ransley and Neufeld,^[81] Opie and Grant,^[82] and Eichenauer, Hattenbach, and Pebler^[83] developed equations to determine the solubility of hydrogen in molten aluminum (Fig. 33). Table 22 compares the results of those calculations.

$$\text{Log } S = 1.961 - (3042 / T) \text{ (solid aluminum)} \quad [83]$$

where S is the solubility of hydrogen in cm^3 per 100 g of metal and T is temperature in K.

Figure 34 shows the solubility of hydrogen in solid aluminum. During melting, hydrogen can be introduced into molten aluminum from the following sources: from gas

entrapped on the oxide film of the solid before melting, from reaction of aluminum with moisture that is in the atmosphere over the melt, or from reaction with moisture in the refractory containing the melt.

TYPICAL CHARACTERISTICS AND APPLICATIONS

The first wrought aluminum alloy has been produced in the USA in 1888. This alloy was designated as 1100 alloy.

The various grades of pure metal were utilized directly as wrought products for specific applications in the early development of the industry. For instance the alloy EC (electrical conductor) had a minimum aluminum content of 99.45%. 1145 aluminum alloy is used for foil production. Chemical composition of some aluminum alloys is shown in^[84] and typical characteristics and applications in Table 23.^[5]

An important application of pure aluminum is as cladding, to improve resistance to corrosion of heat treatable alloys or to improve finishing characteristics of non-heat-treatable alloys.

Abstract

Pulse on time, pulse frequency, peak current, and base current are the important parameters to be optimized in pulsed current tungsten inert gas (PCTIG) welding of Al–SiC metal matrix composite. Experiments were designed and conducted using the L_9 orthogonal array technique. The regression equation was developed using Design Expert® statistical software package to predict the weld center's micro hardness, yield strength, ultimate strength, elongation (%), bending load, weld depth, weld width, cooling rate, and peak temperature near the weld zone of Al-8% SiC composite, welded using PCTIG welding. Correlation coefficient shows 0.9 for all the mechanical properties. This showed that the regression equation and the mathematical model developed were adequate. Analysis of contour plot, interaction effect, signal-to-noise ratio, and mean response were developed, the influence of each pulsed current parameter was evaluated at each level, and the percentage of influence was calculated by using pulsed current parameters. Ultimate tensile strength and bending load values depend on the microstructure. When the cooling rate is higher, fine microstructures are observed due to grain refinement; higher tensile strength and bending load are also observed. Due to the decreased cooling rate, coarse microstructures are observed, which result in poor tensile strength and bending load. PCTIG welding parameters are responsible for the change in the cooling rate of the weld zone. The optimization of the PCTIG welding parameters shows that the peak current and base current should be 160 and 60 A, respectively. Pulse on time is recommended to be 50%–55% and pulse frequency to be 5 Hz.

Keywords: Al–SiC composite; Mechanical properties; Optimization; PCTIG welding.

INTRODUCTION

Manufacturing of Al–SiC Composite

In the metal matrix composite, aluminum is extensively used as the metal matrix material because of its ease in processing and lower melting point. SiC, TiB₂, TiC, B₄C, and fly ash are the commonly used reinforcements present in the aluminum metal matrix.^[1,2] Reinforcements such as SiO₂, MgO, and Al₂O₃ are mixed in a liquid-state aluminum metal matrix through liquid-state mixing method and successfully manufactured.^[3,4] Here, an increase in the weight percentage of SiO₂, MgO, and Al₂O₃ shows an increase in the ultimate strength, yield strength, and hardness and a reduction in ductility and toughness (reduced impact strength).^[5,6]

Aluminum silicon carbide composite (Al–SiC) has improved strength, good wear resistance, and good stiffness-to-weight ratio. Aluminum metal matrix composite with SiC

can be manufactured through the stir casting method, and the optimum level of SiC on the aluminum metal matrix is 25% because it gives maximum hardness and impact strength.^[7,8] To increase the SiC content on the aluminum metal matrix, preheating temperature should be increased to an optimum level that will give maximum strength and ductility to the material. Al-30% SiC shows a sudden failure during compressive load; 25% SiC on the aluminum metal matrix is more brittle in nature.^[9,10] Hardness and tensile strength are increased with an increase in the weight percentage of SiC content in the aluminum metal matrix, and strain is decreased with an increase in the weight percentage of SiC.^[11,12]

It can also retain these mechanical properties in elevated temperatures other than the base material. Stir casting is a more suitable and economical method used for the manufacturing of Al–SiC composite compared to other manufacturing processes such as powder metallurgy route. Al- α -S3N4 can be prepared by using the powder

metallurgy^[13,14] technique, and the maximum densification is achieved in the sintering temperature of 660°C. Here, the mechanical alloying method is more suitable than all other methods through the result of hardness of various samples prepared using different manufacturing techniques^[15] and spray coating process. Discontinuous fiber metal matrix composite can be manufactured economically by using stir casting method, which is suitable for mass production of any shape but it is costly,^[16] whereas powder metallurgy is economical for manufacturing the components of comparatively smaller sizes. Spray coating of fiber on the metal matrix is also another economical way of production.^[17,17] Stir casting could be achieved by making minor modifications in the conventional casting process.

Tungsten Inert Gas Welding

Tungsten inert gas (TIG) welding is the clean and high-quality welding process in arc welding. It is more suitable for welding stainless steel, aluminum, magnesium, and titanium. In this method, an arc is formed from nonconsumable electrode tungsten, and a filler rod is added separately. Due to this arrangement, arc length has a constant standoff distance, which gives an uninterrupted arc.^[18] This arc energy is used for melting base material and filler rod and for joining each other. Shielding gas such as argon or helium is used to shield the weld pool to avoid oxidation and to get clean and high-quality weld.^[19]

When a filler rod is not added during TIG welding, it is called autogenous TIG welding. This is used to evaluate the mechanical behavior and microstructural characteristics of the weld material.

Existing Problem

Gas tungsten arc welding (GTAW), also known as TIG welding, yields high-quality weld than other arc welding processes. Nonferrous metals require high-quality weld with reduced defects and improved mechanical properties of the weld, which shows that TIG is a more suitable welding process. However, its shallow weld penetration causes lesser production rate.^[18] An increase in weld passes through thick sections leads to higher input^[19] in the weld, reducing the weld strength by producing the coarse grain microstructure.^[20] The optimum welding current of Al–SiC coating on Mg alloy is 150 A because it gives higher hardness below and above optimum current; hardness gets decreased at a welding speed of 200 mm/min.^[20]

Welding of Al–SiC composite using TIG welding has poor weld mechanical properties. This is due to higher heat input in Al–SiC, which leads to dissociation of SiC and forms (aluminum carbide) Al_4C_3 + (silicon) Si. Al_4C_3 phase is more brittle in nature. This phenomenon is explained next.

Addition of filler alloy material with Al-5%Mg and Al-5%Si on Al alloy with 25% SiC on pulsed TIG will eliminate the Al_4C_3 intermetallic phase which is harmful to cause the weld joint to become more brittle and weak.^[22] Adding of Al–Si filler rod greatly depresses the harmful reaction such as Al_4C_3 formation by SiC with Al metal matrix composite; due to this tensile property, it is significantly improved. A fractured specimen of the welded sample in the annealed condition shows ductile fracture.^[18] Al_4C_3 phase formation during the welding of Al–Ti metal matrix with SiC composite is the reason for failure during the tensile testing. This phase is more brittle and weak; this Al_4C_3 phases increases with an increase in SiC on the Al–Ti metal matrix composite.^[19] Addition of Ti as an alloying filler material to Al–SiC eliminates the Al_4C_3 harmful interface; it leads to an increase in the tensile strength and ductility.^[21] An increase in weld power and reinforcement will lead to higher porosity in the weld due to low wettability, and the formation of Al_4C_3 is the reason to brittle failure during tensile testing due to its brittleness.^[23] These results show the considerable loss in weld strength and ductility. Restricting Al_4C_3 formation during TIG welding on the Al–SiC composite improves its strength and ductility. To restrict the formation of aluminum carbide, lesser heat input is needed during TIG welding.^[24]

Solving Methods for Poor Mechanical Properties of Weldments of Al–SiC Composite

Reduced heat input during the TIG welding has a chance to achieve fine grain size in the weld zone and to reduce the residual stress in the heat-affected zone; restricting the Al_4C_3 intermetallic phase formation in the weld zone can improve the quality of the weld. The following variants are used to overcome the problems of TIG welding:

Pulsed current tungsten inert gas (PCTIG) welding—It reduces the heat input, increases the cooling rate, has a fine grain structure in the weld zone, and improves the weld strength.^[25]

Activated tungsten inert gas welding—It increases the weld penetration, reduces the number of passes during multi-pass welding, reduces the residual stress, and improves the weld strength.^[26]

LITERATURE REVIEW

Effect of PCTIG Welding Parameters

PCTIG welding shows an improved mechanical behavior compared to TIG welding. Improved mechanical properties on PCTIG welding give a fine grain microstructure, whereas those on constant current TIG welding give a coarse grain structure.^[27]

During PCTIG welding, the peak current gives adequate penetration, the base current is responsible to maintain stable arc, and the pulse frequency and pulse on time give enough time to transfer heat from the arc to the weld material during the peak current time and cool down the weld pool during the base current time and transfer heat from the weld zone to the heat-affected zone and also to the base material region. This reduces the width of the heat-affected zone and thermally induced stresses. During PCTIG welding, due to the heat input difference between the peak current and the base current, weld pool cools immediately and higher heat concentration on the weld pool is reduced. This gives a fine grain microstructure in the weld zone. The fine grain size has increased grain boundaries that gives the improved mechanical behavior for PCTIG welded samples. The major problem in the welding of aluminum is hot cracking; this can be reduced by reducing the heat input and choosing a correct filler material.

Tensile properties, fatigue properties, impact toughness, and hardness are increased to achieve a fine equiaxed grain microstructure in the weld zone by reducing the heat input. Due to reduced heat in the weld zone, heterogeneous nucleation sites will survive in the weld pool, which converts columnar dendritic grains into fine equiaxed grains. Liquation cracks in the heat-affected zone acts as the strong initiation site for solidification cracks in the weld zone. Healing of liquation cracks through back filling reduces solidification cracks in the weld zone. Pulsed current and arc oscillation techniques give a fine equiaxed grain structure that resists the hot cracking through the increased grain boundaries, but continuous current tungsten inert gas welding (CCTIG) gives a columnar grain structure which has lesser grain boundaries.

The following literature shows the improvement of mechanical properties through grain refinement on different grades of aluminum alloys during the PCTIG welding process:

- Effect of the pulsed current method on the tensile behavior of aluminum alloy 6061 and aluminum alloy 7075 leads to a finer equiaxed grain structure in GTA welds. Grain refinement is the reason for an increase in fatigue crack growth resistance and fatigue life. Simple post-weld aging treatment applied to the joints is found to be beneficial to increase the fatigue crack growth resistance of the welded joints.^[28]
- During PCTIG welding, a finer and more equiaxed grain structure is achieved in GTA and GMA welds. But in conventional TIG welding, a columnar grain structure is achieved. This grain refinement leads to an increase in tensile strength and tensile ductility on aluminum alloy 7075.^[29]
- Yield strength, ultimate tensile strength, and hardness of the weld zone and HAZ of PCTIG are higher than those of the continuous current TIG welded sample.

Residual stress is also lower for PCTIG than for CCTIG due to reduced heat input.^[30]

- Effect of the peak current and frequency will increase the pitting corrosion behavior, and that of the base current and pulse on time will decrease the pitting corrosion on pulsed current GTAW (PCGTAW) in AA7075.^[31]
- The weld zone of CCTIG has prone to hot cracking tendency due to the columnar dendritic microstructure; this hot cracking tendency can be reduced by refining the grain structure through the change in the peak current-to-base current ratio. Pulsed current gives relatively a fine equiaxed grain structure in GTAW and GMAW, but continuous current produces a coarse columnar grain structure.^[32]
- PCGTAW has lower grain size than pulsed current gas metal arc welding (PCGMAW), continuous current gas tungsten arc welding (CCGTAW), and continuous current gas metal arc welding (CCGMAW), and thus, the fatigue properties of GTAW joint are higher than those of other welded joints. Pulsed current parameters give a finer and more equiaxed grain structure in GTA compared to PCGMAW, CCGTAW, and CCGMAW, which results in higher tensile strength and yield strength with higher hardness. Due to magnetic arc oscillation, the grain size is reduced. Frequency of magnetic arc oscillation is the major contribution for the grain refinement, and due to reduced grain size, the ductility of the welded joint has comparatively increased with respect to the conventional TIG welded joint.^[33]
- In welding, the peak current gives adequate penetration and bead contour,^[33] whereas the base current maintains stable arc.
- Pulse frequency gives enough time to transfer the heat from the weld zone and heat-affected zone to the base material region.^[34] This in turn reduces the width of the heat-affected zone and thermally induced stresses.^[35]

From the literature,^[36] it is clear that the optimized PCTIG welding parameters give reduced heat input, higher cooling rate, and fine grain microstructure. This improves the weld strength in aluminum alloys compared to normal continuous current TIG welding. Thus, this shows the significance of optimizing the PCTIG welding parameters.^[37] Among the above methods, pulsed current method can be used in real-time industrial applications with minimum modifications in the existing system.^[38]

Optimizations of PCTIG Welding Parameters

Before optimizing the PCTIG welding parameters, PCTIG welding parameters' working limit should be evaluated. During PCTIG welding, the peak current gives adequate penetration, the base current is responsible to maintain

stable arc, and the pulse frequency and pulse on time give enough time to transfer from the arc to the weld material.^[39] Using L8 orthogonal array, experiment (four factors and two levels), yield strength, ultimate strength, hardness, and elongation are measured. Using regression equation with the parameters such as peak current, base current, welding speed, and frequency to achieve the maximum yield strength, ultimate tensile, hardness, and elongation^[40] This L27 (four factors, three levels) full factorial design optimizes the parameters such as welding current, welding speed, arc amplitude, and arc frequency of the arc oscillation.^[41]

The pulsed current welding parameters can be optimized by using various methods such as response surface method, Hooke and Jeeves algorithm, and Taguchi orthogonal array method. To study the outcome of PCTIG welding parameters such as pulse on time, pulse frequency, peak current, and base current, mathematical models such as empirical models and regression equations have to be developed. The following literature shows the effect of PCTIG welding parameters on the mechanical behavior and material characteristics. It also shows the techniques used to optimize the PCTIG welding parameters by using response surface method, genetic algorithm, artificial neural network (ANN), Hooke and Jeeves algorithm, and Taguchi orthogonal array method.

- To find the working limits of PCTIG welding parameters, designing the experimental conditions is based on the full factorial design on AA6061.^[42,43] Here, the yield strength and ultimate strength are directly proportional to the peak current and pulse frequency, and inversely proportional to the base current and pulse on time.^[43] It was proved using the regression equation developed using C program for mathematical models.^[42]
- Peak current has higher influence than other parameters such as pulse on time, frequency, and base current on tensile strength, which is predicted through the mathematical model, and PCTIG welding parameters are optimized using response surface methodology (RSM)^[44] on magnesium alloy AZ31.
- Grain size and hardness are predicted through the mathematical model developed during PCTIG welding using RSM on titanium alloy.^[45]
- An overall introduction to the design of experiments and the techniques used to minimize the experimental is explained for its cost-effectiveness and to analyze the parameters and their levels of interaction effect between them.^[46]
- Mathematical model is developed for PCTIG welding, and validation experiments are also conducted to verify the model. Peak current has higher influence on tensile strength than the other parameters, which is predicted through the mathematical model developed during

PCTIG welding using RSM on Inconel 625 nickel alloy.^[47]

- Weld width, depth, and peak temperature of the weld pool are measured using sensors on the weld pool. Using ANN, the responses such as the width and depth of penetration are predicted. They are also validated using the mathematical model.^[48]
- Multiple linear regression technique is used to optimize the process parameters of TIG welding for predicting the depth and width of the weld zone using the genetic algorithm.^[49] RSM, genetic algorithm (GA), ANN, Taguchi, and factorial methods are most commonly used to optimize the welding parameter and develop the mathematical model in TIG and PCTIG welding.^[50]
- The optimization techniques are combined to achieve error-free mathematical model. Weld front and back width and weld front and back height are predicted using the conventional regression model, GA-NN, and backpropagation neural network (BP-NN), and their results are compared.^[51]
- Genetic algorithm and RSM are used to reduce the angular distortion by GTAW on stainless steel. The model is developed using RSM, and the optimized values through GA give the validated model.^[52]
- Mathematical model is developed using RSM for optimizing the TIG welding parameters such as welding current, gun angle, welding speed, and gas flow rate to predict the hardness and angular distortion.^[53]
- Experiments are conducted on AA6061 by using the RSM method, and the optimum PCTIG parameter values are evaluated by Hooke and Jeeves algorithm to achieve higher tensile strength and hardness.^[54]

Pulsed current parameters	Effect		
	Desirable limit	Higher than the desired limit	Lower than the desired limit
Peak current	Weld depth or weld penetration	Excessive penetration and burn through	Inadequate penetration
Base current	To make welding arc stable	Unstable arc and arc wandering	Shorter arc length leads to discontinuous weld
Pulse on time	Weld surface free from arc splatters	Weld bead appearance similar to CCTIG	Poor weld bead surface appearance
Pulse frequency	To get better weld bead appearance	Arc splatters observed	Weld bead appearance similar to CCTIG

EXPERIMENTAL WORK FOR OPTIMIZING PCTIG WELDING PARAMETERS ON AL–SiC COMPOSITE

Autogenous PCTIG welding is performed on Al-8%SiC composite material with a plate thickness of 5 mm using ADOR CHAMPTIG 300 AD welding machine.

Experimental runs are decided using four factors and three levels as given in Table 1. Using Taguchi L9 orthogonal array, nine experiments are designed and various conditions are furnished in Table 2. Other welding parameters considered during welding are provided in Table 3.^[55]

During welding, the thermocouple was placed 10 mm away from the weld center and 30 mm away from the welding starting place to acquire data for time–temperature profile. The data are acquired using data acquisition

system (DAQ), which consists of LabView software coupled with National Instrument NI cDAQ 9174 kit employing a temperature-acquiring module NI 9211 as shown in Fig. 1. PCTIG welded samples are shown in Fig. 2.

The flowchart in Fig. 3 shows the procedure for optimizing the PCTIG welding parameter through mechanical testing such as micro hardness, tensile test, bend test, thermal profile, and weld profile of welded samples, and the empirical model used to study the effect of pulsed current parameters on weld characteristics predicts the weld properties and optimizes the PCTIG welding parameters. Tensile-tested samples before and after testing are shown in Figs. 4 and 5.^[56]

RECOGNITION AND IDENTIFICATION OF PCTIG WELDING PROCESS PARAMETERS

From the above literature, it had proved that the PCTIG welding parameters such as pulse on time, pulse frequency, peak current, and base current have influence on tensile strength,^[57] weld profile,^[59] micro hardness,^[60] thermal profile,^[61] and bending load.^[62]

To know the working limits of the PCTIG welding parameters, on a 5-mm plate of Al–SiC composite, from trial runs the results were observed and tabulated in Table 4.

RESULTS OBSERVED

The results for PCTIG welding are shown in Table 5 and Figs. 6–8.

MATHEMATICAL MODEL

Statistical and mathematical techniques can be used for developing empirical relationships. Using these techniques, the influence of parameters on responses can be studied easily. It can also be used for optimizing the conditions based on the desired response and also be employed for predicting the response. Experimental design was done in Design–Expert 7 statistical software package using a Taguchi L9 orthogonal array. Regression equation and correlation coefficients were also developed using Design–Expert 7 statistical software. Peak current, base current, pulses on time, and pulse frequency are the functions of responses, namely, ultimate strength, yield strength, elongation (%), bending load, weld center micro hardness, weld depth, weld width, cooling rate, and peak temperature. The empirical model developed using the regression equation includes the main factors and first-order interaction of all factors. This can be expressed in the form of first-order polynomial equation as specified in the following equation:

Table 4 PCTIG welding parameters and levels—Effect

Pulsed current parameters	Effect		
	Desirable limit	Higher than the desired limit	Lower than the desired limit
Peak current	140–160 A—weld depth or weld penetration	Above 160 A—excessive penetration and burn through	Below 140 A—inadequate penetration
Base current	40–60 A—to make welding arc stable	Above 60 A—unstable arc and arc wandering	Below 40 A—shorter arc length leads to discontinuous weld
Pulse on time	40%–60%—weld surface free from arc splatters	Above 60%—weld bead appearance similar to CCTIG	Below 40%—poor weld bead surface appearance
Pulse frequency	2–10 Hz—to get better weld bead appearance	Above 10 Hz—arc splatters are observed	Below 2 Hz—weld bead appearance similar to CCTIG

$$R = Z_0 + Z_1 + Z_2 + Z_3 + Z_4 + Z_{12} + Z_{23} + Z_{41} + Z_{24} + Z_{13} + Z_{34} \quad (1)$$

where R is the response such as weld center micro hardness; Z_0 is the average response; and $Z_1, Z_2, \dots, Z_{34}$ are the regression coefficients.

The regression coefficients depend on the main factors and interaction of factors. Regression coefficient can be solved using Design-Expert 7 statistical software to obtain regression equations and predict the weld center micro hardness.

Correlation coefficient r^2 shows how nearer the predicted values are to the experimental values. Correlation coefficients for regression equations are shown in Table 6.

Table 6 Regression equation and correlation coefficient

Description	Regression equation (<i>R</i>)	Correlation coefficient (<i>r</i> ²)
Ultimate tensile Strength	$R = 104.73 + (11.50 \times A) + (0.82 \times B) - (1.59 \times C) + (4.13 \times D) + (11.53 \times A \times B) + (1.45 \times B \times C) + (17.95 \times C \times D)$	0.94
Yield strength	$R = 94.20 + (6.66 \times A) - (2.29 \times B) + (0.75 \times C) + (5.10 \times D) + (14.07 \times A \times B) - (7.39 \times B \times C) + (8.55 \times C \times D)$	0.92
Elongation (%)	$R = 9.65 + (0.99 \times A) + (0.24 \times B) + (0.57 \times C) - (0.26 \times D) + (2.25 \times A \times B) + (2.15 \times B \times C) + (1.42 \times C \times D)$	0.90
Bending load	$R = 1.21 + (0.24 \times A) + (0.04 \times B) + (0.16 \times C) + (0.31 \times D) + (0.03 \times A \times B) - (0.02 \times B \times C) + (0.52 \times C \times D)$	0.99
Micro hardness	$R = 66.15 + (0.17 \times A) + (2.29 \times B) + (2.27 \times C) + (1.01 \times D) + (6.44 \times A \times B) + (2.07 \times A \times C) + (1.78 \times B \times C)$	0.99
Bending load	$R = 1.21 + (0.24 \times A) + (0.04 \times B) + (0.16 \times C) + (0.31 \times D) + (0.03 \times A \times B) - (0.02 \times B \times C) + (0.52 \times C \times D)$	0.99
Weld depth	$R = 1.89 + (0.47 \times A) - (0.06 \times B) + (0.24 \times C) + (0.03 \times D) + (0.15 \times A \times B) + (0.05 \times A \times C) + (0.11 \times B \times C)$	0.98
Weld width	$R = 5.74 + (0.45 \times A) + (0.24 \times B) + (0.35 \times C) - (0.37 \times D) - (0.13 \times A \times B) + (0.15 \times A \times C) - (0.27 \times B \times C)$	0.98
Cooling rate	$R = 14.34 - (1.81 \times A) + (2.66 \times B) - (2.34 \times C) - (3.50 \times D) + (2.62 \times A \times B) + (4.66 \times A \times C) - (4.21 \times B \times C)$	0.92
Peak temperature	$R = 377.05 + (15.31 \times A) + (8.63 \times B) + (13.95 \times C) + (24.57 \times D) + (54.22 \times A \times B) - (3.74 \times A \times C) - (7.04 \times B \times C)$	0.90

Note: *R* is the response such as weld center micro hardness; *A* is the peak current; *B* is the base current; *C* is the pulse on time; *D* is the pulse frequency.

Correlation coefficients have higher values, showing a significant effect on the main factors and their interactions with responses. This can be checked using analysis of variance (ANOVA).

$$r^2 = \frac{\sum (Y_{\text{predicted}} - Y_{\text{average}})^2}{\sum (Y_{\text{experimental}} - Y_{\text{average}})^2} \quad (2)$$

where r^2 is the correlation coefficient, $Y_{\text{predicted}}$ is the predicted value of the response, and $Y_{\text{experimental}}$ is the experimental value of the responses.

The correlation coefficient can be calculated using the predicted and experimental values under the same experimental condition (Eq. 2).

Mean response analysis and signal-to-noise (S/N) ratio analysis are carried out with the help of Minitab 13 statistical software for generating the main effect and interaction effect plots using Eqs. 3 and 4.

Mean response analysis is used to calculate the actual mean value using the below equation and compare with the predicted mean value. This gives individual mean values among the responses observed.

Mean response equation

$$\text{Var}(\hat{\alpha} + \hat{\beta}x_d) = \sigma^2 \left(\frac{1}{m} + \frac{(x_d - \bar{x})^2}{\sum (x_i - \bar{x})^2} \right) \quad (3)$$

Predicted response

$$\begin{aligned} \text{Var}\left(y_d - [\hat{\alpha} + \hat{\beta}x_d]\right) &= \sigma^2 + \sigma^2 \left(\frac{1}{m} + \frac{(x_d - \bar{x})^2}{\sum (x_i - \bar{x})^2} \right) \\ &= \sigma^2 \left(1 + \frac{1}{m} + \frac{(x_d - \bar{x})^2}{\sum (x_i - \bar{x})^2} \right) \end{aligned} \quad (4)$$

Confidence interval

$$100(1 - \alpha)\% \quad (5)$$

$$y_d \pm t_{\frac{\alpha}{2}, m-n-1} \sqrt{\text{Var}} \quad (6)$$

$$\alpha + \beta x_d \quad (7)$$

S/N ratio analysis is used to find out the S/N value between the factors and levels. This S/N ratio analysis is carried out using the three conditions shown in Table 7.

ANALYSIS OF RESULTS

Microstructure

From Fig. 9, the following results are observed. PCTIG welding condition 1 showed a fine grain microstructure in

Table 7 Equations for S/N ratio analysis

Conditions	Goal of the experiment	Formula
Larger is better	Maximize the response	$S/N = -10 \times \log(\Sigma(1/Y^2)/n)$
Smaller is better	Minimize the response	$S/N = -10 \times \log(\Sigma(Y^2)/n)$
Nominal is best	Target the response and you want to base the S/N ratio on standard deviations	$S/N = -10 \times \log(\sigma^2)$

**Fig. 9** Microstructure 1 for PCTIG welded samples

the weld zone and a reduced grain size in HAZ than other PCTIG welding conditions. PCTIG welding condition 3 showed a coarse grain structure that is similar to CCTIG welded microstructure. Intermediate grain size was found for both fine and coarse microstructures in PCTIG welding condition 2. Figure 10 showed the microstructure for PCTIG welding conditions 4, 5, and 6. Here, PCTIG welding condition 4 showed an intermediate grain size for both fine and coarse microstructures similar to PCTIG welding condition 2. A fine grain microstructure was found for PCTIG welding conditions 5 and 6 in the weld zone. In Fig. 11, a fine grain microstructure was found for PCTIG welding condition 9 in the weld zone. For PCTIG welding

conditions 7 and 8, a coarse grain microstructure was found in the weld zone.

As a result, these nine PCTIG welding conditions were classified into four types:

- PCTIG welding parameter with no effect (conditions 7 and 8).
- PCTIG welding parameter with minimum effect (conditions 3 and 4).
- PCTIG welding parameter with normal effect (conditions 2, 5, and 6).
- PCTIG welding parameter with maximum effect (conditions 1 and 9).

Fig. 10 Microstructure 2 for PCTIG welded samples

Fig. 11 Microstructure 3 for PCTIG welded samples

Analysis of Error Graph

The percentage of error between the experimental value and the predicted value is found using the regression equation. These values are plotted in the error graph. Figures 12–20 show the graphs with experimental values and predicted value for ultimate strength, yield strength, elongation (%), bending load, weld center micro hardness, weld depth, weld width, cooling rate, and peak temperature near the weld zone. From the graphs, it is clear that the percentage of error is below 5% between the experimental value and the predicted value. This shows that the consistent results were obtained using

regression equations for ultimate strength, yield strength, elongation (%), bending load, weld center micro hardness, weld depth, weld width, cooling rate, and peak temperature near the weld zone. Hence, the regression models are valid within the range of pulsed current parameters.

Analysis of Contour Plots

Ultimate Tensile Strength

In Figs. 21–23, the pulse frequency parameter is considered to be constant, i.e., 5 Hz. Hence, these results can be compared.

Fig. 12 Experimental value vs. predicted value for ultimate tensile strength

Fig. 21 Ultimate tensile strength (pulse on time = 60% and pulse frequency = 5 Hz)

Fig. 22 Ultimate tensile strength (pulse on time = 50% and pulse frequency = 5 Hz)

Fig. 23 Ultimate tensile strength (pulse on time = 40% and pulse frequency = 5 Hz)

In Fig. 21, the ultimate tensile strength is 120 MPa when the pulse on time is 60%, the peak current is 160 A, and the base current is 60 A. In Fig. 22, a higher ultimate strength of 133 MPa is observed, while the parameters such as the pulse on time, the peak current, and the base current are 50%, 160 A, and 60 A, respectively. Figure 23 shows an ultimate tensile strength of 120 MPa when a pulse on time of 40%, a peak current of 140 A, and a base current of 40 A are applied. Figures 22, 24, and 25 show the results with a constant pulse on time of 50%. In Fig. 25, when a pulse frequency of 2 Hz is applied, a comparatively lower ultimate tensile strength of 117 MPa is observed. When a pulse frequency of 10 Hz is applied, an ultimate strength of 120 MPa is observed as depicted in Fig. 24. A maximum tensile strength of 133 MPa is obtained when a pulse frequency of 5 Hz is applied, as shown in Fig. 22. For all the above observations, the peak current and base current are 160 A and 60 A, respectively.

This decrease in ultimate tensile strength is due to lesser cooling rate. This shows that the difference in the peak current and the base current has its influence on the cooling rate, which directly affects the ultimate tensile strength.

Ultimate tensile strength (pulse on time = 50% and pulse frequency = 2 Hz).

Yield Strength

On comparing Figs. 26–28, the pulse frequency is the same, i.e., 5 Hz. In Figs. 26 and 28, the yield strength is the same, i.e., 107 MPa when 60% pulse on time and 40% pulse on time are applied. At 50% pulse on time, the maximum yield strength is 115 MPa, as shown in Fig. 27. All these results are obtained when the peak current is 160 A and the base current is 60 A. Now, Figs. 27, 29, and 30 are compared considering the pulse on time as 50%. When

Fig. 24 Ultimate tensile strength (pulse on time = 50% and pulse frequency = 10 Hz)

Fig. 25 Ultimate tensile strength (Ppulse on time = 50% and pulse frequency = 2 Hz)

Fig. 26 Yield strength (pulse on time = 60% and pulse frequency = 5 Hz)

Fig. 27 Yield strength (pulse on time = 50% and pulse frequency = 5 Hz)

Fig. 28 Yield strength (pulse on time = 40% and pulse frequency = 5 Hz)

Fig. 29 Yield strength (pulse on time = 50% and pulse frequency = 10 Hz)

Fig. 30 Yield strength (pulse on time=50% and pulse frequency = 2 Hz)

the pulse frequency of 2 Hz is applied, the yield strength is 101 MPa as shown in Fig. 30. This indicates that the pulse frequency of 2 Hz does not have much effect on the yield strength. From Fig. 27, when considering a pulse frequency of 5 Hz, the yield strength will be 115 MPa. When the pulse frequency is increased to 10 Hz, it will result in a slightly reduced yield strength of 109 MPa as depicted in Fig. 27. So it is clear that the maximum yield strength is achieved when the pulse on time is 50%, the pulse frequency is 5 Hz, the peak current is 160 A, and the base current is 60 A.

Elongation (%)

From Fig. 31, elongation (%) is 12.11% when the pulse on time, pulse frequency, peak current, and base current are 60%, 5 Hz, 160 A, and 60 A, respectively. When the pulse on time is 40%, the pulse frequency is 5 Hz, the peak current is 140 A, and the base current is 40 A, elongation (%) will be 12.56% as indicated in Fig. 32.

Elongation (%) is observed to be 11.79% in Fig. 33 and 11.91% in Fig. 34 when the pulse frequencies are 10 and 2 Hz, respectively. The other parameters include a peak current of 160 A, a base current of 60 A, and a pulse on time of 50%. The maximum elongation (%) observed in Fig. 35 is 15.54% when the pulse on time is 50%, the pulse frequency is 5 Hz, the peak current is 160 A, and the base current is 60 A.

From the above results, it is clear that the elongation (%) directly depends on the pulse frequency parameters rather than the other PCTIG welding parameters. This is because a slightest variation in pulse frequency results in a significant reduction in elongation (%) compared to the change in the effect of the pulse on time on elongation (%).

Bending Load

Results of Figs. 36 and 37 show that the bending load is 1.18 kN when the pulse on time is considered to be 50%,

the peak current is 160 A, and the base current is 50–60 A with pulse frequencies of 10 and 2 Hz, respectively. From Fig. 38, it is observed that the bending load is 1.35 kN for the pulsed current parameter conditions such as a peak current of 160 A, a base current of 60 A, a pulse on time of 60%, and a pulse frequency of 5 Hz. When the pulse on time is 40%, the peak current is 150–160 A, the base current is 40–50 A, and the pulse frequency is 5 Hz, the bending load will be 1.47 kN as shown in Fig. 39. A maximum bending load of 1.68 kN is observed for a peak current of 160 A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz as depicted in Fig. 40.

From the above results, it is clear that a slightest variation in pulse frequencies below and above 5 Hz results in reduced bending load. Pulse on time, peak current, and base current differences also have great significance on the bending load.

Micro Hardness

When the pulse on time is 50% and the pulse frequency is 2 Hz, the resultant micro hardness value obtained is 69 HV as shown in Fig. 41. The peak current value is 140 A and the base current value is 40 A during this condition. Figure 42 shows a micro hardness value of 79 HV for a pulse on time of 50%, a pulse frequency of 5 Hz, a peak current of 160 A, and a base current of 60 A. Further, when the pulse frequency is increased to 10 Hz, keeping all other parameters constant, the micro hardness obtained is 77 HV. This shows that when the pulse frequency is increased above 5 Hz, the micro hardness will get reduced as depicted in Fig. 43. With the pulse on time being 40% and 60% and keeping other parameters constant as mentioned previously, the micro hardness values obtained will be 77 and 73 HV as shown in Figs. 44 and 45, respectively. This decrease in micro hardness is due to lesser cooling rate. This shows that the difference in the peak current and the

Fig. 44 Micro hardness (pulse on time = 40% and pulse frequency = 5 Hz)

Fig. 45 Micro hardness (pulse on time = 60% and pulse frequency = 5 Hz)

base current has its influence on the cooling rate, which will directly affect the micro hardness.

Weld Depth

Figures 46–48 show that the weld depths are 2.21, 2.26, and 2.23 mm, respectively, when the pulse on time is 50% and the pulse frequency values keep changing from 2, 5, to 10 Hz. It shows that the pulse frequency does not have much influence on the weld depth. In Fig. 49, a minimum weld depth of 1.91 mm is observed when the pulse on time is 40% and the pulse frequency is 5 Hz. With the pulse on time of 60% and the pulse frequency of 5 Hz, the weld depth is 2.63 mm as shown in Fig. 50. From Figs. 46–50, it is clear that the maximum weld depth is obtained during a peak current of 160 A and a base current of 60 A. An increase in pulse on time from 40% to 60% shows an

increased weld depth. This shows that an increase in heat input will result in an increase in weld depth.

Weld Width
